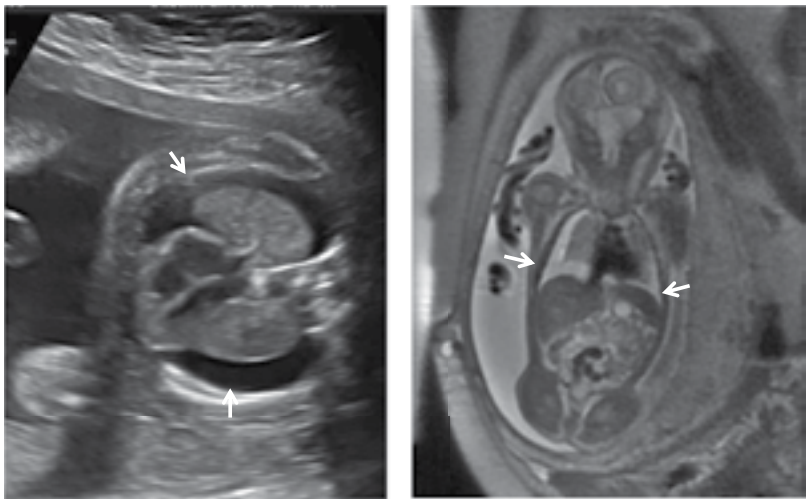
FETAL PLEURAL EFFUSION

Fetal pleural effusion (or fetal hydrothorax) is a rare condition, with an incidence of 1/7300 to 1/15000.[2] Increased use of fetal sonography over the past decades has led to an increased frequency of diagnosis. Fetal pleural effusion is detected by prenatal ultrasound as a unilateral or bilateral anechoic space in the thorax surrounding the lungs (Figure 41.3). Pleural effusion can be an isolated finding or occur in association with other conditions.

The clinical course varies from complete spontaneous resolution to a progressive phenotype leading to the development of hydrops fetalis and perinatal death. If the pleural effusion is severe enough to increase intrathoracic pressure, it reduces cardiac output, leading to polyhydramnios and pulmonary hypoplasia. This results in potential cardiac failure, in utero



(a) (b)

Lungs are partially compressed in the presence of large bilateral pleural effusions. The cardiothymic silhouette remains in normal position, no mediastinal shift. Also, there is no evidence of hydrops.

demise, premature delivery, and neonatal death. Fetal pleural effusion is usually detected around a gestation age of 21–24 weeks. Nine to twenty-two percent of fetuses will have spontaneous regression, often in the second trimester. In contrast to neonatal pleural effusions, fetal pleural effusions are associated with a high mortality rate. In those fetuses with progression, overall survival rate is 22%–53%. Lower survival rate is seen in pleural effusion associated with structural/chromosomal abnormalities or hydropic fetuses, younger gestational age at diagnosis, higher volume effusions, and bilateral disease.[2,38,39]

Diagnostic workup for a fetal pleural effusion should include fetal ultrasound, fetal MRI, fetal echocardiography, karyotyping, maternal blood count, type and screen with antibody status, and virology screening for Toxoplasmosis, Other Agents, Rubella, Cytomegalovirus, and Herpes Simplex (TORCH) and parvovirus B19.

The management of fetal pleural effusion has been controversial, and the optimal treatment approach remains unclear. Prenatal intervention for selected rapidly progressive cases with a high risk of perinatal morbidity and mortality is accepted (Figure 41.4). Current fetal interventions include (1) thoracocentesis using a 20G spinal needle to aspirate the pleural effusion, (2) thoracoamniotic shunting for reaccumulated fluid after aspiration, and (3) fetal intrapleural injection of OK-432. Therapeutic outcomes in the literature showed a 60%–65% overall survival rate irrespective of the different treatment options, with worse outcome if there is a presence of hydrops. However, as with any fetal therapy, there are the inherent risks of inducing preterm labor, preterm premature rupture of membrane, intrauterine infection, bleeding, and maternal or fetal organ trauma. In particular, with any shunt procedure, there are the risks of shunt displacement and blockage of the shunt.[40]

OTHER PLEURAL EFFUSIONS

Hemothorax

Although massive hemothorax is uncommon, accidental injury to the intercostal artery during thoracentesis or closed intercostal drainage can result it intrapleural bleeding. Hemothorax has been reported as a complication of a variety of congenital malformations (e.g., sequestration, patent ductus, and pulmonary arteriovenous malformation) and of subclavian vein catheters.[41] It is also an occasional manifestation of intrathoracic neoplasms, blood dyscrasias, and bleeding diatheses. Additionally, it can occur spontaneously in neonates, sometimes in association with a pneumothorax. Symptoms reveal respiratory embarrassment similar to that seen in tension pneumothorax. However, the percussion note is dull, and chest radiographs show opacification. More importantly, the infant may show signs of hypovolemic shock. Blood transfusion and urgent tube thoracostomy generally provide adequate control of bleeding. To avoid sudden circulatory collapse, transfusion should precede intercostal drainage. It is very rare in neonates; however, urgent thoracotomy and identification and securing of the bleeding site might be required, if massive blood loss continues.

Empyema

Owing primarily to improved antibiotic treatment of chest infections, empyema (purulent effusion) has become a rare condition in infants. The most common cause of empyema is a pneumonia caused by organisms such as *Staphylococcus aureus, Staphylococcus pneumoniae*, and *Staphylococcus*

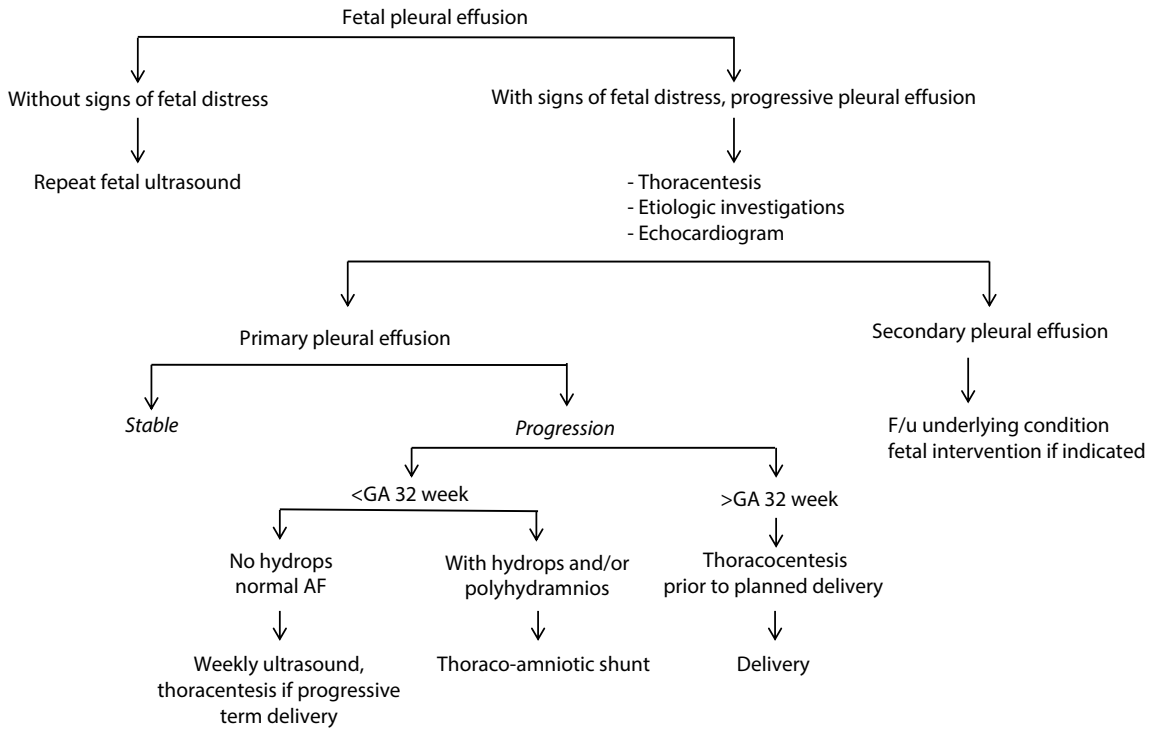


Figure 41.4 Algorithm of management principles for fetal pleural effusions. AF: amniotic fluid; f/u: follow-up; GA: gestation age.

pyogenes. It may, however, be incurred through the introduction of skin bacteria during thoracentesis or thoracotomy. Empyema may also be accompanied by anaerobic infection. Symptoms include indications of respiratory distress in addition to abdominal distension, lethargy, and at times, a septicemic state. Diagnosis is suspected by chest radiographs in which the effusion and pneumonic process are identified. Ultrasonography during diagnostic thoracentesis if helpful in specifically localizing loculated fluid collection. Prior to beginning a course of antibiotic therapy, a fluid specimen taken during thoracentesis is sent for a Gram stain and aerobic and anaerobic culture. Although most cases resolve with effective intercostal tube drainage, fibrinolysis, and a prolonged period of systemic administration of antibiotics, anaerobic infection tends to be multilocular and may thus require debridement and, in rare instances, decortication.

Congenital malformations of the lung

SHANNON M. KOEHLER AND KEITH T. OLDHAM

INTRODUCTION

Congenital lung abnormalities are uncommon and diverse in their presentations. However, all those who care for infants and children must have an appreciation for the diagnosis and treatment of these anomalies because the potential consequences can be life threatening. In order to understand the pathophysiology of these malformations, one must have a basic understanding of the embryology of lung development as well as lung anatomy and respiratory physiology, which are presented below. Classical lesions including congenital lobar emphysema (CLE), congenital pulmonary airway malformation (CPAM), pulmonary sequestration, and bronchogenic cysts will be discussed along with several more uncommon lung anomalies.

Embryology

During the fourth week of gestation, the human embryo develops a diverticulum of the ventral foregut, which forms the primordium of the respiratory system.[1,2] This is mainly of endodermal origin; however, cartilaginous and muscular elements will be derived from the splanchnic mesoderm that surrounds the primitive foregut.[2] As the laryngotracheal diverticulum grows caudad, it becomes separated from the foregut by the lateral tracheoesophageal folds, which fuse to form the tracheoesophageal septum at the end of the fifth gestational week.[1,2] Thus, the dorsal esophagus and the more ventral trachea and lung buds are defined. The larynx, which is formed from the fourth and sixth branchial arches,[1] maintains communication between the pharynx and the trachea.

The lung buds penetrate the coelomic cavity by caudal growth, resulting in the formation of pericardioperitoneal canals on either side of the foregut.[1,2] The expanding lung buds eventually come to nearly fill these canals, with the small residual spaces becoming the primitive pleural cavities.[2] The right lung bud divides into three lobes, whereas the left forms two by the end of the embryo's fifth week.[2] The bronchi continue successive dichotomous division, and by the end of the sixth month of gestation, 17 generations of subdivisions have formed.[2] This period is also the time at which terminal bronchioles and alveoli are forming. An additional six divisions of the terminal airways will occur during early postnatal life[2]; however, lung development probably does not cease until about 8 years of age.[2] Thus, development of conductive airways is essentially complete by the end of the second trimester, while terminal airways and alveoli, which are the site of gas exchange, continue to develop in late fetal life and early childhood. As one considers the various clinical lesions and their therapeutic options, this perspective is critical.

The pulmonary vascular system develops in parallel to the lung parenchyma. As the lung buds form, a pulmonary vascular plexus arises.[3] The lung buds branch to give rise to the pulmonary tree, while the mesenchymal tissue condenses to form the pulmonary vessels by vasculogenesis.[3] Over the course of fetal development, the pulmonary vasculature expands by vasculogenesis and angiogenesis.[3] It is not until 36 weeks gestational age that the pulmonary capillary networks remodel to position the capillary and alveoli in close proximity to allow optimal gas exchange.[3]

Anatomy

A brief discussion of clinically relevant anatomy is appropriate; several excellent references are available for a more detailed review.[4,5] As seen in early gestational development of the lungs, the mature right lung is composed of three lobes in contrast to the two lobes of the left.[4–7] The carina is positioned at the level of the fourth or fifth thoracic vertebral body in the term infant.[6] The mainstem bronchus of the right lung follows a straighter, more caudad course and is usually shorter and larger in diameter than that of the left.[4,6] This accounts for the preference of aspirated material to enter the right lower lobe or the posterior segment of the right upper lobe. Similarly, the configuration explains the propensity for right mainstem bronchus intubation during endotracheal tube placement.[6]

The vascular supply of the trachea, bronchi, and lung parenchyma is systemic in origin and separate from the pulmonary arterial circulation.[6] The trachea is supplied by branches of the paired inferior thyroid arteries, which anastomose with the bronchial blood supply derived from the aorta on the left and the third intercostal artery on the right.[6] Venous drainage is via the azygous and hemiazygous systems.[6] This systemic arterial supply and its accompanying venous drainage generally follow the segmental architecture of the lung and bronchi.[6]

The pulmonary arterial circulation is dedicated to gas exchange. Oxygen-depleted blood arrives at the lung through the pulmonary artery.[7] The blood travels through the lungs to the capillary network where it releases carbon dioxide and picks up oxygen during respiration.[7] The oxygenated blood then leaves the lungs through pulmonary veins, which return it to the left heart, completing the pulmonary cycle.[7]

Congenital lobar emphysema

CLE is characterized by air trapping and overdistention of one or more lobes, which are otherwise anatomically normal. This distention causes compression of adjacent normal lung parenchyma and can result in mediastinal shift and cardiorespiratory compromise (Figure 42.1).

A specific etiology of this disorder cannot be demonstrated in up to half of reported cases.[8–10] The underlying cause in the remaining 50% can be divided into extrinsic and intrinsic subtypes.[9] Extrinsic causes include compression from anomalous or enlarged blood vessels, congenital heart disease, mediastinal lymphadenopathy, bronchogenic and enteric cysts, and tumors.[6,8,9,11] Intrinsic causes encompass structural deficiency or absence of supportive cartilage in the affected lobar bronchus,[6,8,9,11] thereby causing expiratory collapse of the conducting airway with impedance to expiratory flow.[8] Partial obstruction from mucous plugging, extensive mucosal proliferation, inflammation, infection, bronchial torsion, bronchial atresia, or aspirated materials are other possible intrinsic causes of CLE.[6,8,9,11]

Figure 42.1 Congenital lobar emphysema. Chest x-ray in a 3-day-old infant who presented with respiratory distress, showing marked hyperinflation of right upper lobe.

CLE is a rare disorder with an incidence of 1 in 20,000 to 1 in 90,000 births.[12,13] Historically, it has been considered a disease of the Caucasian population with a male predominance (2:1 to 3:1)[6]; however, a more recent study suggested a higher incidence in non-whites,[14] and another study failed to show a male predominance.[15] It is most common in the left upper lobe (40%–50%), with other sites affected less frequently: right middle lobe (30%–40%), right upper lobe (20%), and lower lobes (1%).[8,11] In 14% of infants, CLE is associated with congenital heart disease.[13,16] The most common cardiac anomalies are large left-to-right shunts or pulmonary hypertension, but tetralogy of Fallot and patent ductus arteriosus have also been described.[16] Routine echocardiography is recommended in the screening evaluation of these patients. Rarely, other anomalies in the renal, gastrointestinal, musculoskeletal, or cutaneous systems may be seen.[10]

Presentation and diagnosis

CLE is rarely diagnosed on prenatal ultrasound.[10] The main finding on ultrasound is increased echogenicity of the lungs, but this is generally subtle and can also be seen in pulmonary sequestration, CPAM, or upper airway obstruction.[10] Also, similar to pulmonary sequestration and CPAM, there are reports of decreasing size of the lesion during pregnancy.[10] In more severe cases, mediastinal shift, polyhydramnios, or fetal hydrops can be appreciated on prenatal ultrasound.[10] Recently, reports of diagnosis of CLE with fetal magnetic resonance imaging (MRI) have been emerging and may prove useful in prenatally identifying the etiology in some cases.[17,18]

If symptomatic, patients with CLE typically present in the neonatal period with respiratory distress.[9,10,15,17] Only ~25% of patients are diagnosed at birth, ~50% by 1 month of age, and nearly all by 6 months of age.[8,11] Rarely, older children or adults may present with milder symptoms such as recurrent respiratory infections or cough, or may be asymptomatic altogether.[19,20] Depending upon the severity of adjacent lung compression, cyanosis and respiratory failure may occur, and this is noted in 12% of patients with CLE.[15]

On exam, the patient with CLE will demonstrate signs consistent with a hyperinflated lobe, including thoracic and respiratory asymmetry, decreased breath sounds, and percussive hyperresonance of the ipsilateral chest. Findings of mediastinal shift such as tracheal deviation and displacement of the cardiac apical impulse are relatively late clinical signs.

Chest roentgenography is the initial and often the sole diagnostic maneuver of choice (Figure 42.1).[9] There is increased radiolucency over the affected side, with accompanying atelectasis of adjacent compressed parenchyma and a flattened ipsilateral hemidiaphragm. Mediastinal displacement to the contralateral side may also be apparent. The chest radiograph should be inspected closely to

differentiate between CLE and tension pneumothorax, which may have similar presentation and appearance but vastly different management. Contrary to CLE, tension pneumothorax has no peripheral lung markings. In the first hours after birth, the affected lobe may still be filled with fetal lung fluid and therefore have the appearance of a mass with fluid density.[11] Some authors advocate ventilation–perfusion radioisotope scanning as a useful adjunct to the chest radiograph.[11] Others advise the use of computed tomography (CT) or MRI.[11]

Treatment

Rapid and judicious bronchoscopy should also be employed to rule out intrinsic subtypes that may be treated without need for lobectomy. However, the surgeon must be available for emergent decompressive thoracotomy, particularly when positive-pressure ventilation is employed at procedures such as anesthesia induction or bronchoscopy.[11] If a source of endobronchial obstruction cannot be found and corrected, then the often-progressive nature of this lesion, as well as the risk of respiratory failure, dictate lobectomy of the affected lobe in infants. This is done via either muscle sparing thoracotomy or thoracoscopy. For the older child without symptoms, this approach can be reasonably tempered. Reconstructive procedures such as bronchoplasty or segmental bronchial resection are generally not appropriate, as the bronchial defects may not be focal or readily localized. In addition, lobectomy in the infant population is very well tolerated,[21–23] and bronchial reconstruction in the newborn is fraught with technical limitations.

Polyalveolar lobe

Polyalveolar morphology mimics CLE in its clinical presentation. This is a descriptive histologic term that refers to unusual and abnormal anatomic findings characterized by an increase in the number of alveoli in a particular lobe.[11] This is in contrast to CLE where alveolar histopathology is normal except for overdistention. Similar to CLE, polyalveolar lung results in expiratory air trapping and lobar overdistension with respiratory compromise.[11] The diagnosis and treatment of polyalveolar morphology are not different than for CLE. Likewise, because CLE and polyalveolar lung cannot be distinguished clinically or radiologically, these are often grouped together as congenital lobar overinflation.[11]

Congenital pulmonary airway malformations

CPAMs are a rare group of cystic lobar hamartomatous lesions, but represent up to 50%–70% of the bronchopulmonary foregut malformations in some reports.[24] The lesions are generally large, firm, multicystic masses that are composed of terminal respiratory structures, usually bronchiolar in origin and lacking normal alveoli.[9] They are typically unilobar and unilateral, and do not have a predilection for a certain side of the lung,[9] but are most common in the lower lobes.[11]

The precise pathogenesis of CPAM is unknown. Several theories exist regarding the origin of CPAM including anomalous or developmental arrest of terminal bronchiole maturation, while others believe it is due to focal pulmonary dysplasia.[25] Similar to the pathogenesis, the timing of development is debated with pathological and radiologic evidence at 5–22 weeks gestational age. Histology demonstrates ciliated cuboidal or columnar cells lining the cysts, with a lack of organized architecture; usually no cartilage is present (Figure 42.2). These malformations typically communicate with the normal bronchial tree and have a normal vascular supply, although aberrant systemic vasculature, sometimes derived from the aorta, has been described.[26]

The incidence of CPAM, in general, is reported at 1 to 10,000 to 1 in 35,000.[9] They do not have an increased incidence in a certain race or sex.[9] Associated anomalies are uncommon with CPAM.[11]

The classification of CPAMs has undergone constant modification in the past four decades. Adzick et al.[27] described macrocystic and microcystic or solid lesions based on prenatal ultrasound imaging. The contemporary classification scheme proposed by Stocker and colleagues grouped CPAMs into five distinct pathologic types (Table 42.1).[28,29] This classification system, which is based on the presumed site of development of the malformation, carries both descriptive and prognostic significance.[28,30] Type 0 CPAMs, previously termed acinar dysplasia, represent only 1%–3% of CPAMs.[29] The lesions appear solid on prenatal ultrasound and are composed of multiple small cysts less than 0.5 cm.[29] Unlike most other forms of CPAMs, these patients may have other congenital anomalies.[29] These patients have a poor prognosis, and some references even state that it is incompatible with life.[29]

Type 1 CPAMs are the most common subtype and account for about 65% of cases.[28,29] This form typically has one dominant cyst, in one lobe, measuring in size from 0.5 to 10 cm.[28,29] At birth, the cyst expands and compresses the adjacent healthy lung, flattens the diaphragm, and may cause mediastinal shift.[28] Thus, affected patients usually

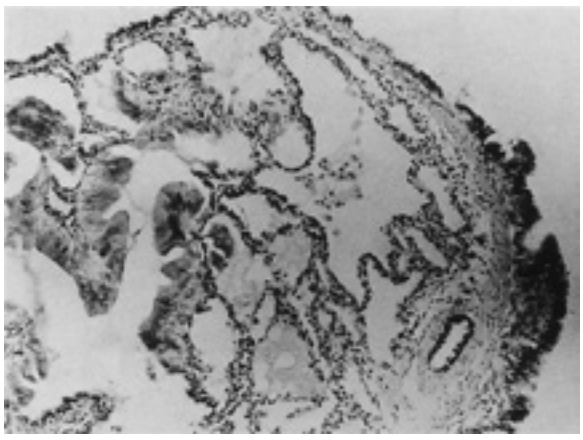

Figure 42.2 Type 1 CPAM. Histology specimen of lung showing mucinogenic cells, papillary epithelium, and disorganized, irregular alveoli.

Table 42.1 Pathologic features of CPAM

Stocker's type	0	1	2	3	4
Approximate frequency (%)	1–3	>65	20–25	8	2–4
Cyst size (max, cm)	0.5	10.0	2.5	1.5	7.0
Epithelial lining (cysts)	Ciliated; pseudostratified; tall columnar	Ciliated; pseudostratified; tall	Ciliated; cuboidal	Ciliated; cuboidal	Flattened; alveolar lining cells

present with respiratory distress in the immediate postnatal period.[28] Type 1 CPAM patients usually have a good prognosis[29] with lobectomy.[28] If the lesion is small, patients may not present until later in life with recurrent infections.[28]

Type 2 CPAMs represent 10%–20% of CPAMs.[28,29] These lesions have multiple smaller cysts ranging in size from 0.5 to 2.0 cm. They can be seen in patients with pulmonary sequestration[30]; however, these lesions are also associated with other congenital anomalies (cardiovascular, genitourinary, and musculoskeletal) in up to 50% of patients.[28–30] The prognosis for these patients is often related to these associated anomalies, which may be severe, such as bilateral renal agenesis.[28] If patients do not have severe associated abnormalities, they may present with respiratory distress similar to Type 1 CPAMs, and treatment in this situation would be surgical resection.[28]

Type 3 lesions only represent ~5% of CPAMs and are more solid than cystic in nature.[29] Prenatally, these lesions often grow to a significant size, which leads to pulmonary hypoplasia and mediastinal shift. If this scenario progresses, it continues to polyhydramnios and hydrops, which can result in fetal demise.[30]

Type 4 CPAMs are also macrocystic and are made up of large cysts of size up to 10 cm.[28,29] This subtype represents 10–15% of all CPAMs, and also like Type 1 CPAMs, these patients have a generally good prognosis.[28] Unlike Type 1, which are bronchial, these lesions are peripherally oriented, and as a result, patients may present with respiratory distress in the neonatal period or with a pneumothorax in older children.[28,29] As with the other forms of CPAMs, the treatment of choice is surgical resection. It is important to examine these lesions closely intraoperatively as they can be confused with pleuropulmonary blastoma, which would have a solid component.[28]

Regardless of subtype, CPAM volume ratio (CVR) has been used as a prognostic indicator.[31,32] The volume of the lesion is calculated by measuring three dimensions of the CPAMs on prenatal ultrasound, and the ratio is determined by dividing by the head circumference to correct for gestational age.[32] Crombleholme et al.[32] demonstrated that a CVR ≤ 1.6 was low risk and >1.6 was at increased risk for developing hydrops.[32]

Presentation and diagnosis

Since the advent of routine ultrasound in obstetric practice, the majority of cystic lung lesions are now discovered prenatally in many institutions in the United States. The location of the stomach aids in differentiation between CPAM and congenital diaphragmatic hernia (CDH), although prenatal MRI may be needed for definitive diagnosis in difficult cases.[33] Serial ultrasonographic exams may demonstrate shrinkage or even spontaneous resolution in 15%–40% of fetal CPAMs.[22,34,35]

Physiologic consequences of CPAM can be seen antepartum and occur secondary to mediastinal shift and compression of normal lung tissue. Large masses, especially those involving type 2 or 3 lesions, can result in nonimmune hydrops fetalis and fetal demise. The polyhydramnios is thought to result from esophageal compression, preventing fetal swallowing of amniotic fluid; the hydrops results from mediastinal shift from the mass effect, diminishing cardiac output by vena caval obstruction.[22] Either finding during pregnancy is associated with poor outcome.

In the neonatal period, some infants will demonstrate tachypnea, dyspnea, cyanosis, or impending respiratory failure. Although this can be dramatic, numerous series in the literature have demonstrated that only 26%–45% of patients present in this manner.[36] Of the remaining patients, most will present within the first 2 years of life with recurrent or persistent respiratory infections, respiratory distress, pneumothorax, or chronic cough.[36]

As with all bronchopulmonary foregut malformations, the plain chest radiograph is the best initial diagnostic test in the neonate (Figure 42.3). Nasogastric tube position is often helpful to distinguish CPAM from CDH as an intrathoracic stomach

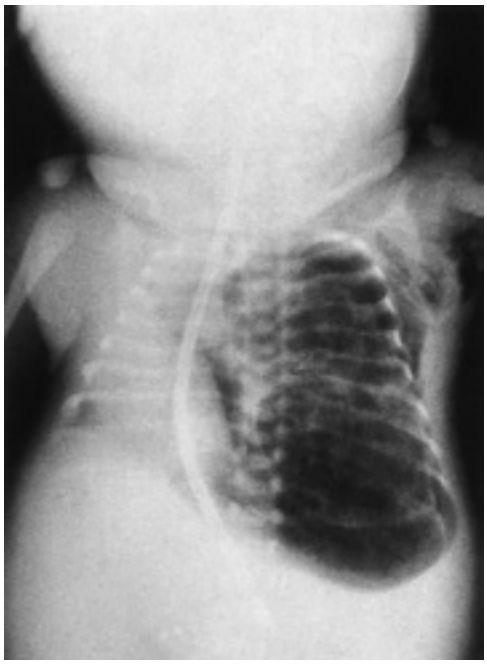

Figure 42.3 Congenital pulmonary airway malformation of the left lung with gross expansion of the lung, marked mediastinal shift to the right, and downward displacement of diaphragm. Note surgical emphysema of left axilla and chest wall, indicating rupture of a cyst.

is quite common with left CDH. The radiographic findings are variable; radiographs taken early in the neonatal period may demonstrate fluid within the lesion, whereas later films may show air-filled cysts.[37] Mediastinal shift, an ipsilateral flattened diaphragm, and compressed adjacent normal lung may also be present, depending on the severity of disease. It is advisable to obtain an axial imaging study, either a CT scan with intravenous contrast or MRI,[37] in all patients with cystic lesions of the chest in order to establish a diagnosis as well as delineate anatomic relationships prior to elective resection (Figure 42.4). Even those who have had spontaneous intrauterine resolution of an apparent CPAM demonstrated by serial prenatal ultrasound should be evaluated with axial imaging following birth, as residual parenchymal abnormalities may be present.[34,35,37]

Treatment

Maternal administration of betamethasone has been a subject of investigation in the fetal treatment of predominantly microcystic CPAM. While the exact mechanism is unknown, a recent study by Peranteau et al.[38] is one of the largest to demonstrate the benefit of prenatal betamethasone in congenital lung lesions. The majority of these fetuses had microcystic CPAM, but the study did include fetuses with large microcystic or solid non-CPAM congenital lung lesions (bronchopulmonary sequestration, CLE, and hybrid lesions). In this 11-year retrospective study, fetuses with a CVR > 1.6 or concern for hydrops were candidates for betamethasone administration.[38] The mothers of these fetuses were given two doses of 12 mg intramuscular betamethasone 24 h apart. In some cases, this course was repeated one or two more times.[38] The majority of patients had reduction in the size of the lesion (82%) and resolution of hydrops (88%) in the single course cohort.[38] While the reduction was not as robust in the multiple course recipients (47% and 56%, respectively), it was still significant compared to nontreated historical controls. Furthermore, the survival rates were 93% and 86% in the single and multiple course patients, respectively, compared to historical controls where

With permission.)

0% with hydrops survived and only 56% with a CVR > 1.6 survived.[38]

Prenatal treatment of macrocystic CPAM has also been advocated. Wilson et al.[39] have studied thoracoamniotic shunts for patients with macrocystic CPAM complicated by hydrops or at significant risk for pulmonary hypoplasia. In this population, they demonstrated increased survival after shunting compared to published reports.[39] Other groups recommend more liberal indications for shunting. Schrey et al.[40] offered thoracoamniotic shunting if fetuses had hydrops, ascites, polyhydramnios, large lesions, or lesions that were rapidly increasing in size. In this study, which included 11 fetuses, 1 hydropic fetus did not survive, but the rest were delivered alive at a mean gestational age of 38.2 weeks.[40] Thoracoamniotic shunting does appear to be a promising intrauterine treatment for macrocystic CPAM; however, further research will be required to determine the exact indications for this fetal intervention.

Ex utero intrapartum therapy (EXIT) procedures have also been utilized as treatment for high-risk CPAM. This involves resection of the CPAM via thoracotomy while maternal–placental–fetal circulation is maintained, followed by delivery of the infant.[41] Cass et al.[42] defined a population of patients with fetal hydrops or a CCAM-volume ratio > 1.6 and persistent mediastinal compression near birth who were selected for the EXIT procedure ($n = 9$) or standard delivery ($n = 7$). In this study, those patients who underwent EXIT procedures had favorable outcomes and survived to discharge, whereas all those in the standard delivery group developed respiratory distress requiring urgent resections and resulted in 28.6% mortality rate.[42] Larger studies are needed to confirm these results and clarify indications for procedure; however, like thoracoamniotic shunting, this procedure shows promise for improved outcomes in fetuses with high-risk CPAM.

Postnatally, the cornerstone of treatment in symptomatic patients with CPAM is complete resection of the abnormal tissue, which usually requires lobectomy. This is done via open, muscle sparing thoracotomy or thoracoscopy. Patients with multilobular disease may benefit from segmental resection if possible, and total pneumonectomy is occasionally required.[43] Prenatal diagnosis of CPAM should prompt referral to a tertiary care center, where critical care support and emergent pediatric surgical care are available. Like infants with CLE, the postnatal phenomenon of breathing or positive pressure ventilation may rapidly precipitate a crisis in CPAM patients if there is progressive distention of the affected lobe. Older children who present with pulmonary infection may be managed acutely with antibiotics, and then undergo subsequent elective lobectomy.

Treatment of asymptomatic patients with CPAMs is somewhat controversial. Some suggest that not all CPAMs require resection. They state that as prenatal imaging is improving, more CPAMs are being diagnosed leading to a new population of asymptomatic CPAM patients with smaller, previously unrecognized lesion. One report offers four arguments against surgery in asymptomatic infants: (1) the natural history of CPAM is not well defined as until recently all were resected; (2) there is morbidity to surgery; (3) the malignant potential is overstated; and (4) there is the possibility of further regression with increasing age.[44] Similar arguments were proposed by Stanton[45] whose group had previously reported that only 5% of patients with congenital lung malformations (85% CPAM) went on to develop symptoms by age 5.[45,46]

Similar arguments were proposed by Ng whose group had previously reported that only 5% of patients with congenital lung malformations (86% CPAM) went on to develop symptoms by age 5.[46] In striking comparison to the Ng et al. study quoted above, Wong et al.[36] found that 86% of patients with asymptomatic CPAM at birth subsequently became symptomatic at a median age of 2 years. When surgical resection was performed electively at 1–3 months of age on patients with asymptomatic CPAM, there is minimal morbidity; however, there was a 47% complication rate when surgical resection was performed after the patients became symptomatic.[36] Likewise, two meta-analyses demonstrated significantly fewer operative complications when resection is performed prior to onset of symptoms.[47,48] Finally, operations performed in presymptomatic patients were associated with potentially parenchyma sparing resection such as segmentectomy with better long-term lung function.[49]

It was also thought that once discovered, these lesions should be removed regardless of symptomatology as malignant transformation with bronchioalveolar carcinoma was estimated to occur in 1% of CPAMs in general.[28,29,50] Furthermore, because bronchioalveolar carcinoma has been found in patients who have had their CPAM removed in infancy, a full lobectomy has been recommended to decrease the risk of bronchioalveolar carcinoma later in life.[28] Thus, for all of the above reasons, lobectomy has been advised in any patient with CPAM. Currently, there are no prospective studies comparing elective surgery with conservative management for asymptomatic patients,[45] and this will be necessary to completely resolve this debate.

Pulmonary sequestration

Pulmonary sequestrations make up 10%–30% of the cystic bronchopulmonary foregut malformations in most reports.[43,51] They are portions of the lung that are isolated from the surrounding parenchyma and have no communication with the normal tracheobronchial tree. In addition, the malformation receives its blood supply from aberrant systemic arterial vessels (Table 42.2).[52] They are classified by whether the sequestration resides within the visceral pleura of the normal lung (intralobar sequestration) or is invested by its own visceral pleura (extralobar sequestration).

Intralobar sequestrations make up the majority (75%) of pulmonary sequestrations, and most commonly involve the posterior basal segments of the left lower lobe.[53] As mentioned, these intralobar lesions are surrounded by normal lung parenchyma and pleura. The arterial supply is usually derived

Table 42.2 Characteristics of pulmonary sequestrations

Characteristic	Intralobar	Extralobar
Incidence	Uncommon	Rare
Incidence ratio	3	1
Sex	Equal	Male 80%
Side	60% left	90% left
Location	Usually in the posterior basal segment	Above the diaphragm, rarely below
Age at presentation and symptoms	Adolescent to young adults, 50% >20 years, recurrent pulmonary infections	Neonate 60%, B1 year, respiratory distress
Associated anomalies	Uncommon	Frequent (>50%), e.g., congenital diaphragmatic hernia (30%)
Diagnosis at neonatal autopsy	None	Frequent
Arterial supply	Systemic—from aorta, large vessels, often a single vessel	Systemic—from pulmonary or aorta, usually small vessels
Venous drainage	Pulmonary—inferior pulmonary vein	Systemic—azygos or hemiazygos vein; rarely portal vein
Anatomical relations	Not separate, within and part of normal lobe	Separate, has its own investment—visceral pleura
Connection with foregut	Very rare	More common
Bronchial communication	Present, small	None

Source: Shamji FM et al. *Surg Clin North Am* 1988; 68: 581–620. With permission.

from aberrant branches of the descending thoracic aorta.[53] Occasionally, intercostal, brachiocephalic, or abdominal aortic aberrant or multiple anomalous vessels are encountered.[53] Venous drainage is usually via the associated pulmonary vein.[53] Although sequestrations are, by definition, nonfunctional and sequestered from the respiratory tree, intralobar sequestrations may communicate with neighboring alveoli in the normal lung via abnormal air spaces, allowing some ventilation and air-trapping within the intralobar lesions.[53] Concomitant anomalies have been described in 11%–13.7% of patients with intralobar sequestration including musculoskeletal, renal, and cardiac anomalies or CDH.[53,54]

Extralobar sequestrations are completely separated from the normal lung and invested by an individual pleura. They are most commonly found on the left side (65%–90%) and in the lower chest (63%–77.4%), with the vast majority in the thoracic cavity (77%–91.7%) but may occur intra-abdominally (8.2%–15%).[52–54] These sequestrations also derive arterial blood supply from the thoracic or abdominal aorta,[54] with up to 20% having an aberrant vessel traversing the diaphragm. Venous drainage into systemic veins, such as the azygous, hemiazygous, or the inferior vena cava, is typical for extralobar sequestrations.[54] Aberrant air-space connections are not present; rather extralobar sequestrations are prone to hemorrhage or arterial-venous shunting, and the patients may present with high-output congestive heart failure.[54] Associated congenital anomalies are very common with extralobar sequestrations and are seen in ~60% of cases.[53,54] CDHs and CPAMs are the most commonly seen anomalies, but a variety of other congenital defects have also been described.[53,55] Unlike intralobar sequestrations, there is a 3 to 4:1 male predominance in most published series of extralobar sequestration.[54]

The embryologic origin of pulmonary sequestrations is unclear and controversial. Generally, extralobar sequestrations are thought to be congenital in origin and a result of either abnormal budding of the tracheobronchial tree or accessory budding of the foregut, or a combination of the two.[54] Some believe that intralobar sequestration has a similar etiology; however, others believe that it is an acquired disease caused by local infection.[54]

Presentation and diagnosis

Although diagnosis of intralobar sequestration is improving, patients with intralobar sequestration often present with pulmonary infections due to abnormal air-space connections with inadequate drainage, or from compressive atelectasis of adjacent parenchyma. This pathophysiology explains why diagnosis is uncommon in infancy, and presentation occurs later in childhood or adulthood with complaints of recurrent or refractory pneumonias, lung abscesses, or hemoptysis.

Extralobar sequestrations, on the other hand, are frequently diagnosed on prenatal ultrasound by identifying the pathognomonic aberrant arterial blood supply on Doppler. If the mass is large, shift of mediastinal structures, fetal hydrops, and fetal demise can occur. Ipsilateral pleural effusions are seen in 6%–10% of cases,[56] and the presence of a large pleural effusion puts the fetus at high risk for pulmonary hypoplasia.[57]

Infants with extralobar sequestration are often asymptomatic at birth. However, even if missed prenatally, due to the frequency of associated anomalies, they are often diagnosed early in infancy during evaluation for these other

problems. Occasionally, these lesions will be identified during surgical repair of their associated CDH.[54] Those 25% that are symptomatic shortly after birth will present with respiratory distress or feeding difficulties.[54] The majority of symptomatic extralobar pulmonary sequestration patients will present with respiratory symptoms or congestive heart failure within the first 6 months of life.[54]

Plain radiographs of the chest will usually demonstrate an intralobar sequestration as a well-defined, triangular, non-aerated, atelectatic mass, or as a cyst with an air-fluid level (Figure 42.5a). Extralobar sequestrations are often difficult to visualize on chest x-ray but most often appear as a left posterior mediastinal mass or triangular retrocardiac density.[54]

In most infants and children with pulmonary sequestration, additional imaging beyond the initial radiographs is recommended. Ultrasound with Doppler (Figure 42.5b), CT angiogram (Figure 42.5c), or MRI provide good anatomic detail and demonstrate relationships to neighboring structures. Importantly, all delineate the aberrant arterial vessels for purposes of diagnosis and preoperative planning. Preoperative upper gastrointestinal contrast study may assist in identifying the rare patients who have anomalous foregut communication with their sequestration, sometimes referred to as communicating bronchopulmonary foregut malformation.[54] Some experienced pediatric surgeons do not routinely do this, relying instead on intraoperative discovery.

Treatment

Fetal interventions are rarely required for pulmonary sequestration, but those complicated by massive pleural effusions may require early intervention. Thoracoamniotic

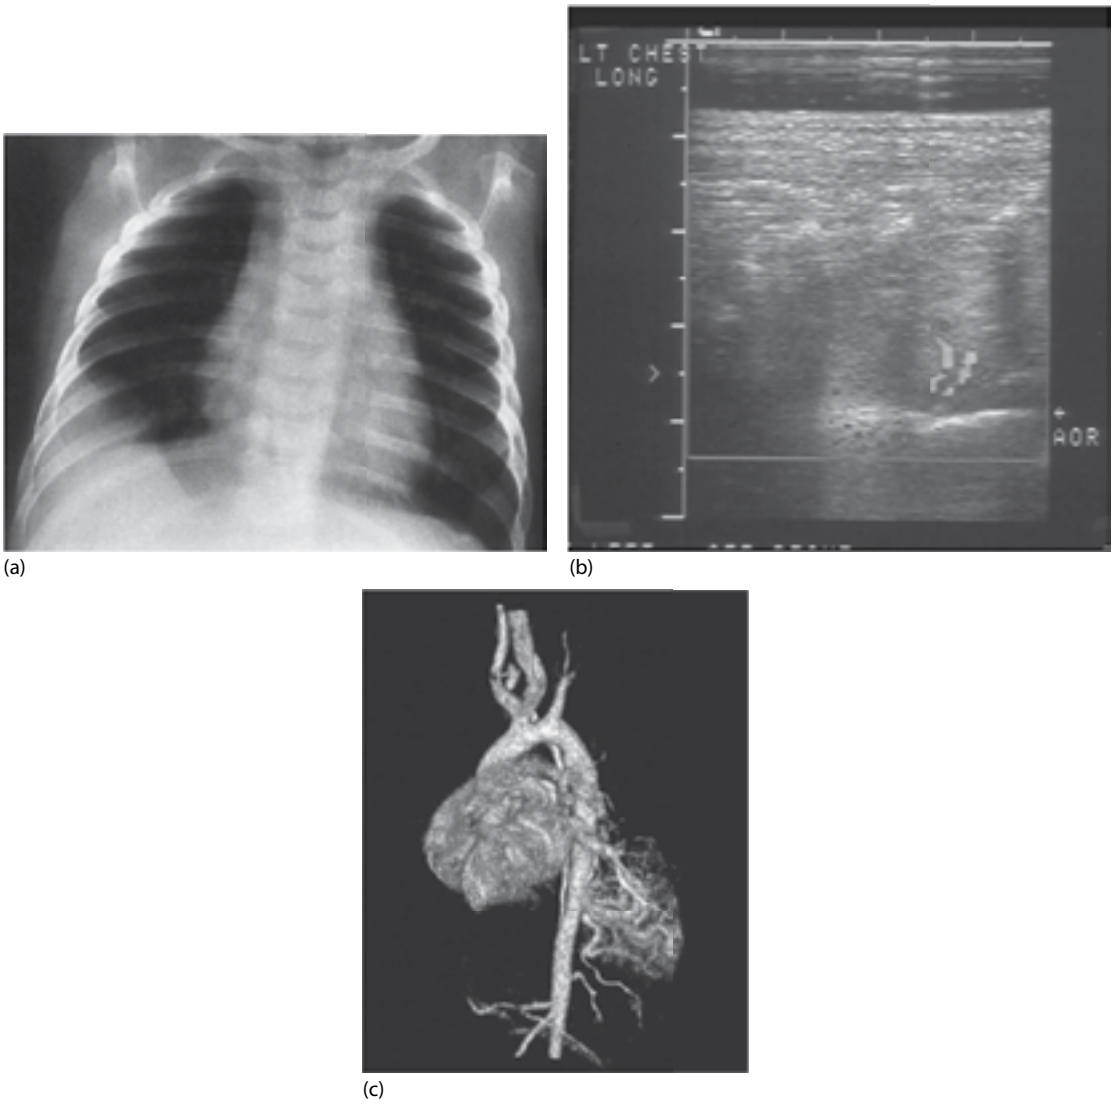

Figure 42.5 Pulmonary sequestration. **(a)** Chest x-ray demonstrates a well-defined mass at base of right lung. **(b)** Prenatal Doppler ultrasound demonstrating two aberrant arterial vessels to extralobar sequestration (arrow). **(c)** CT angiogram demonstrates an enlarged bronchial artery arising from the distal descending thoracic aorta, supplying an intrapulmonary sequestration.

shunts and laser ablation to interrupt the aberrant blood supply to the lesion have both been described.[58] Laser ablation has been shown to cause resolution of the associated pleural effusion and reduction or resolution of the sequestration itself.[57] A more recent retrospective study compared thoracoamniotic shunting to laser ablation and found laser ablation to be more effective, have fewer complications, and possibly reduce the need for postnatal surgery.[59] However, this study was retrospective and only had seven patients in the thoracoamniotic shunting arm and five in the laser ablation arm; thus, further studies are warranted to verify these results.

Postnatal treatment for pulmonary sequestrations consists of excision of the abnormal tissue. Although extralobar sequestrations may be asymptomatic, the cumulative risks of hemorrhage, infection, arteriovenous shunting, and late malignancy have generally been considered to be an indication for resection when diagnosed. This is a point of some controversy in recent years, as some have chosen to observe asymptomatic patients. In patients with extralobar sequestration, surgical resection is a relatively straightforward procedure performed via thoracotomy versus thoracoscopy, or laparotomy versus laparoscopy depending on the location of the lesion. Intralobar sequestration is treated with lobectomy via thoracotomy or thoracoscopy,[60] although in selected cases, segmentectomy may be appropriate. Segmentectomy may be more feasible in situations where prenatal discovery offers opportunity for resection prior to the onset of infectious complications.

A critical element in resection of a pulmonary sequestration is the identification and control of the anomalous systemic arterial blood supply. Reports of unrecognized or uncontrolled hemorrhage from accidental division of the aberrant arteries emphasize this point.[53] This is especially true of vessels with a subdiaphragmatic origin that course through the inferior pulmonary ligament and are prone to retraction into the abdomen when severed or avulsed. Current imaging techniques allow preoperative assessment of the arterial and venous anatomy associated with these lesions, and assist the surgeon in operative planning.

Other important technical points include particular care in identification of the phrenic nerve, which may travel adjacent and lateral to an extralobar sequestration. Abnormal foregut communications, whether diagnosed preoperatively or not, must be carefully sought and controlled appropriately intraoperatively.

More recently, reports have emerged in the literature regarding the use of endovascular embolization as treatment for pulmonary sequestration in infants and children. This is more frequently used in those patients who present with cardiac failure requiring closure of their shunt.[61] These patients will need to be followed long term to determine if they subsequently develop infections, recurrent shunts, or pulmonary hypertension. A randomized controlled trial would be ideal; however, given the selection bias inherent to the treatment of choice, this may prove difficult.

Bronchogenic cysts

Bronchogenic cysts are typically thick-walled, unilocular lesions, which are composed of smooth muscle, cartilage, and mucous glands lined by ciliated columnar epithelium.[60] They are usually simple and contain fluid or mucus.[9] However, air-fluid levels and infection may be seen if there is continuity with the tracheobronchial tree. In contrast to sequestrations, bronchogenic cysts have a normal bronchial blood supply. They arise from the trachea, bronchus, or other conducting airways but have usually lost their connection with the parent structure, although they often remain adjacent. Thus, the majority of bronchogenic cysts are found in the mediastinum (65%–86%).[9,37,62] Bronchogenic cysts can arise during any stage of airway development and can also migrate to subpleural, pericardial, paravertebral, cervical, or retroperitoneal locations if connections are lost with the parent structure; therefore, they can be found in many locations clinically.[9] Though benign, they generally progress to infectious, compressive, or hemorrhagic complications.[63] Rarely, bronchogenic cyst specimens have been shown to undergo malignant change[9,50] including rhabdomyosarcoma.[64]

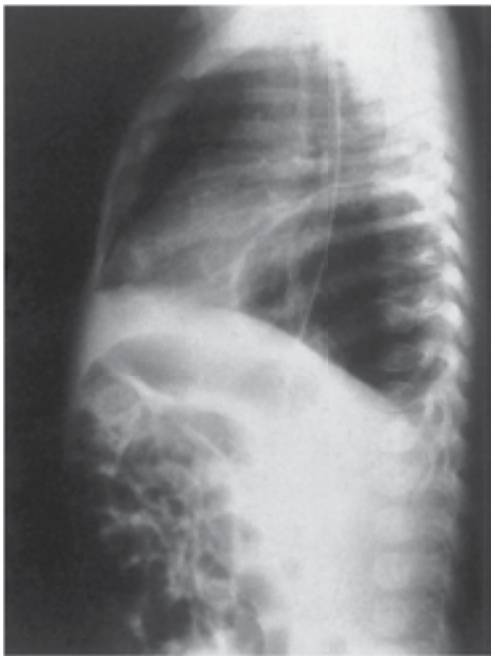
Presentation and diagnosis

Prenatal diagnosis of bronchogenic cysts is occurring with increasing frequency. On ultrasound, these lesions appear as unilocular fluid-filled cysts in the middle or posterior mediastinum.[50]

Postnatally, if symptomatic, the presentation of bronchogenic cysts varies with age of initial symptoms.[60] Infants may present with respiratory symptoms such as dyspnea, cyanosis, or feeding difficulties.[60] These symptoms are related to compression of the adjacent conducting airway with partial obstruction or associated tracheomalacia. Older children generally present with pulmonary infections.[60] Hemoptysis may occur as a result of infection. Rarely, the cyst may enlarge to the point where the mass effect leads to mediastinal displacement, airway compression, compression of normal lung, and cardiorespiratory failure.

Plain chest radiographs typically demonstrate a smooth, spherical, paratracheal or hilar solid mass without calcifications (Figure 42.6). If airway communication or infection is present, an air-fluid level may be seen.[9] Displacement of adjacent airway structures is commonly observed. While these cysts are generally unilocular, a honeycomb appearance can be seen in some forms of this lesion. However, findings on radiographs are generally not specific enough to allow diagnosis. CT or MRI often is necessary to definitively diagnose a bronchogenic cyst and will assist in demonstrating anatomic relationships.[9,63] Contrast esophagram and bronchoscopy are additional modalities by which to identify foregut communication or extrinsic compression.

(a)



(b)

Figure 42.6 **(a)** Chest x-ray showing a large cyst occupying the lower half of the right thorax. **(b)** Lateral view localized the cyst to the lower lobe.

Treatment

If identified prenatally, postnatal excision is recommended. This can generally be done between 4 and 6 months of age.[63] However, acute respiratory decompensation from a large tense bronchogenic or lung cyst may necessitate needle or chest tube thoracostomy as a temporizing measure. Preexisting pneumonias should be treated with preoperative antibiotics. Thereafter, patients can be treated with surgical resection, enucleation, or lobectomy.[9] In patients with stable cysts, simple cystectomy should be performed with oversewing or stapling of any anomalous bronchial communications (Figure 42.7). If a bronchogenic cyst cannot be removed in its entirety, remaining portions of cyst wall may be destroyed with electrocautery. Generally, lateral thoracotomy or thoracoscopy is employed for management of these lesions, although median sternotomy may be appropriate for certain central lesions.[62] The thoracoscopic approach has been used successfully in recent years and may be associated with shorter duration of thoracostomy drainage and hospital stay.[50,63]

Pulmonary hypoplasia, aplasia, and agenesis

Pulmonary hypoplasia refers to the abnormal development of an entire lung or both lungs, resulting in a diminutive and potentially dysfunctional gas exchange organ. The exact pathogenesis is not completely understood, but normal lung development requires a normal thoracic cavity, normal fetal breathing movements, as well as normal amniotic fluid volume and pressure.[65] Pulmonary tissue needs space to grow and expand in the thoracic cavity.[66] If expansion is prevented, developmental arrest during organogenesis sometime after the sixth gestational week will result in a reduction in the number and size of alveoli.[65] Varying degrees of pulmonary hypoplasia can occur, but it may be marked.[66] While primary pulmonary hypoplasia rarely occurs, it is most often a consequence of renal or urinary tract anomalies. Extrinsic compression during gestational development is also commonly seen.[65] A number of intrathoracic mass lesions may cause extrinsic compression of the lung; the most common are CDH, CPAM, and pleural effusions.[65] The physiologic consequences of pulmonary hypoplasia can be severe and include pulmonary hypertension, persistent fetal circulation, and respiratory failure. Extraordinary measures of clinical support are frequently required including high-frequency oscillation, the use of inhaled nitric oxide, and extracorporeal membrane oxygenation.[51,65–67]

Pulmonary agenesis is the complete absence of one or both lungs. This rare congenital anomaly has an estimated prevalence of 24–34 per 1,000,000 live births but is seen on 1 per 10,000–15,000 autopsies.[68,69] The specific cause of this accident of embryogenesis is unknown; however, there is apparent failure of organogenesis at about the time the trachea divides into the two lung buds, early in the fourth week of gestation.[69]

The diagnosis of pulmonary agenesis can often be suggested on prenatal ultrasound. With the addition of color Doppler to demonstrate the absence of the ipsilateral pulmonary artery, definitive diagnosis can be made.[69] Kuwashima and Kaji[70] have suggested that if prenatal ultrasound is indicative of unilateral pulmonary agenesis, fetal MRI should be performed. If (1) the lung is absent, (2) the ipsilateral main bronchus is absent, (3) the ipsilateral pulmonary artery is absent, (4) the unaffected lung has homogeneous, normal intensity, and (5) the abdominal contents are in the abdomen, the diagnosis of unilateral pulmonary agenesis can be made.[70]

Postnatally, bilateral pulmonary agenesis is exceedingly rare and is inevitably incompatible with life. Unilateral pulmonary agenesis may be asymptomatic; however, symptomatic patients may pose difficult neonatal management issues, not only from the standpoint of respiratory insufficiency but

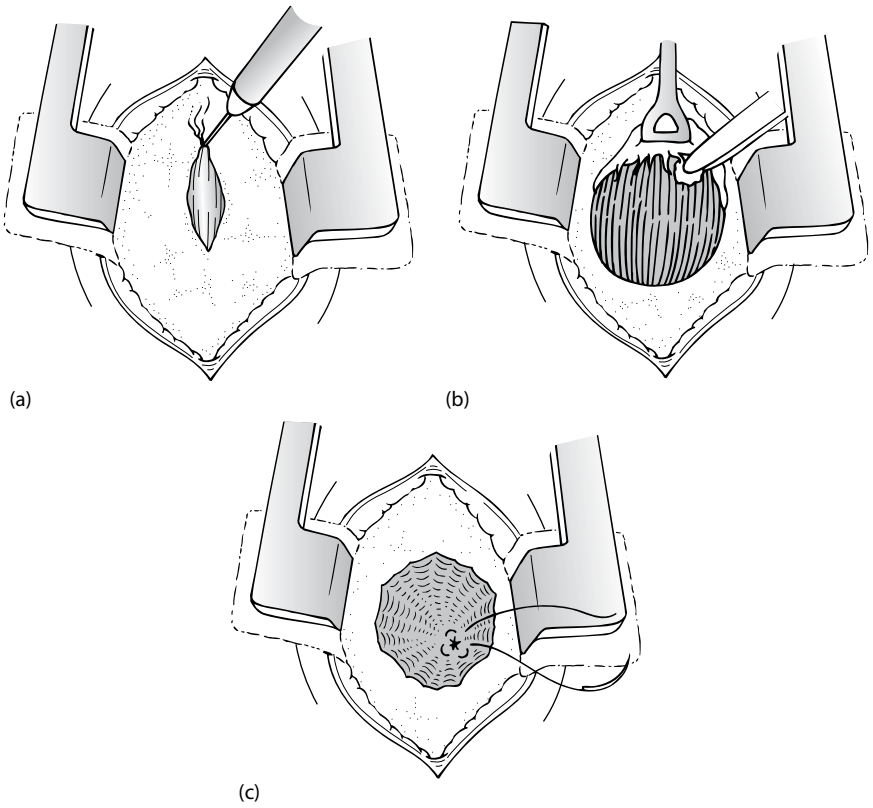


Figure 42.7 Operative technique of lung cystectomy. **(a)** Cyst wall exposed after incising lung tissue just above the cyst. **(b)** Dissection in the plane between the cyst and lung tissue. **(c)** Showing a small bronchus opening into the cyst—the opening is closed by oversewing it.

also because of a high incidence (50%–70%) of associated anomalies.[69] Older children may be asymptomatic or demonstrate nonspecific respiratory symptoms including a history of failure to thrive, exercise intolerance, recurrent respiratory infections, and chest asymmetry or scoliosis. A shift in the location of heart tones and absent ipsilateral breath sounds is demonstrable on physical examination. Chest roentgenograms will demonstrate hyperinflation of the contralateral lung and possibly a fluid-filled ipsilateral hemithorax in the setting of marked displacement of the mediastinum.[69] If the diagnosis had not yet been confirmed, again, the absence of the ipsilateral mainstem bronchus or the pulmonary artery is a definitive finding, and this can be established by endoscopy, echocardiography, axial imaging, or angiography. The prognosis reported in the literature is quite variable, but there is a worse prognosis for those patients with right-sided unilateral pulmonary agenesis. Kayemba-Kay et al.[69] suggest that a normal life can be expected for those patients with left-sided pulmonary agenesis, but this likely depends more on the concurrent congenital anomalies.

LUNG SURGERY IN NEWBORNS

Although a full discussion of thoracic surgery in children is beyond the scope of this chapter, a brief description of surgical technique in neonates is relevant. A number of comprehensive texts are available.[71–73] Lung surgery in neonates is generally similar to that in adults except that the diminutive size, the associated lesions, and the unique pathologic entities require certain special considerations. Of course, the smaller the child is, the more care must be taken in order to avoid technical injury. As with all lung surgery, technical problems may result in serious and irreversible consequences. Collaboration with pediatric anesthesiologists familiar with the unique circumstances of pediatric chest surgery is essential.

Lobectomy

The patient is positioned in the lateral decubitus position, with the upper arm extended and placed over the head (Figure 42.8a). Rolled towels and other positioning devices may be placed in order to optimize stabilization and exposure of the operative field. As always in pediatric surgery, heat loss is a concern, and insulating coverings should be placed over exposed areas without interference to the surgical site. Convective and radiant warmers should also be employed.

Optimal exposure is gained by transverse or oblique incision over the fourth or fifth intercostal space, below and lateral to the nipple to avoid cosmetic and functional damage to the breast tissue. There should be some space between the tip of the scapula and the posterior extent of the incision. This becomes important during closure of the muscle layers, especially if the

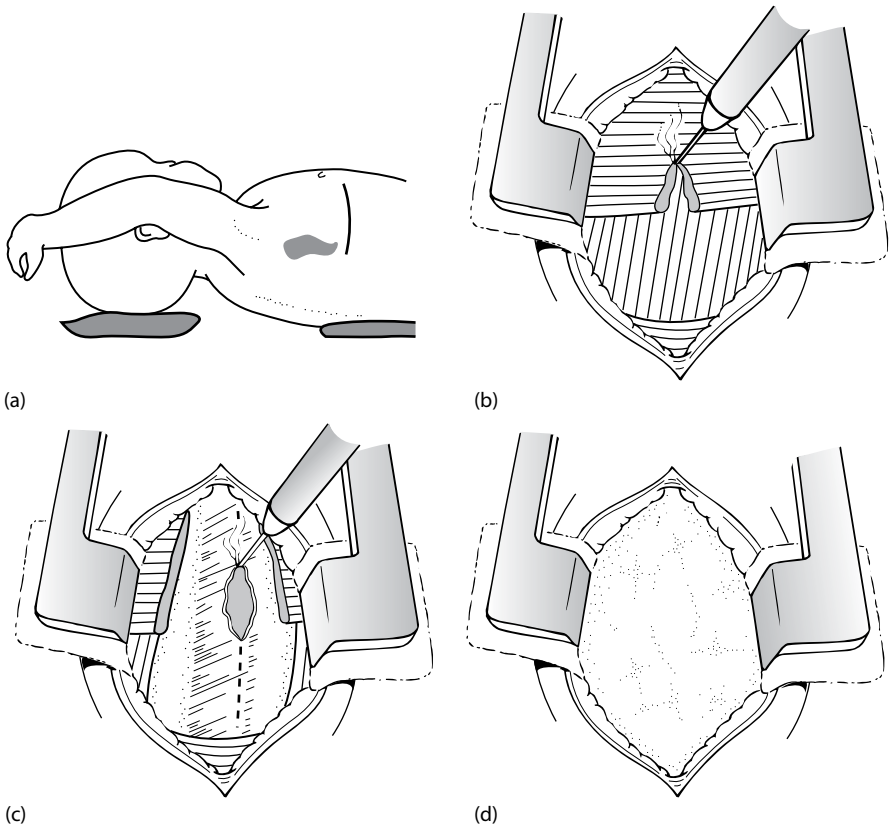

Figure 42.8 Operative technique of thoracotomy: **(a)** transverse lateral incision; **(b)** division of external intercostal muscles; **(c)** division of intercostal muscles along the upper border of the lower rib; and **(d)** retraction of ribs to expose the lung.

incision must be extended posterolaterally. Underlying muscle and subcutaneous tissue is divided along the line of incision (Figure 42.8b) by electrocautery. To limit postoperative morbidity from scoliosis, it is desirable and usually possible to employ a muscle sparing approach, which involves retraction of the serratus anterior and latissimus dorsi muscles, but leaves them intact. The scapula is elevated off the chest wall by retractor to gain exposure, and palpation is used to count the ribs to the correct interspace. In most situations in infants, the highest palpable rib is the second. Generally, the fourth interspace is used for a lobectomy, although the fifth can be used effectively as well. The incision is then continued with electrocautery just superior to the lower rib of the selected intercostal space to avoid damage to the neurovascular bundle that runs along the inferior border of each rib (Figure 42.8c). Care must be taken when entering the pleura to avoid injury to the lung parenchyma. A rib spreader is then placed to facilitate retraction (Figure 42.8d). The incision may then be extended anteriorly or posteriorly if further exposure is needed. It is clear that thoracoscopic techniques in practiced hands yield similar good results as do open techniques.

The following technique and illustrations are described for an left upper lobectomy; however, the principles are the same for any lobe resection. Gentle lateral and inferior traction on the lobe exposes the hilum. The visceral pleura is carefully incised circumferentially, exposing the hilar structures (Figure 42.9). Meticulous dissection reveals the left main pulmonary artery as it courses under the aortic arch (Figure 42.10) and crosses the left upper lobe bronchus. Important structures to note are the left phrenic nerve anteriomedially along the mediastinum, and the recurrent laryngeal nerve branching from the vagus under the aortic arch. A review of segmental anatomy of the lung describes four main arterial branches supplying the left upper lobe; however, this can be variable. These are individually encircled, ligated, and divided. This is typically done with heavy silk and using double proximal

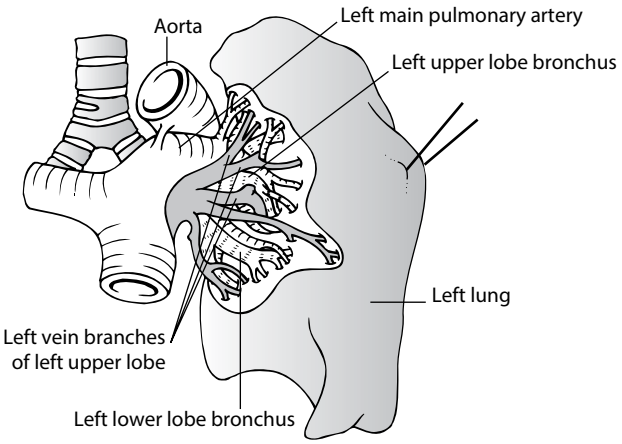

Figure 42.9 Normal anatomy of the left lung hilum containing the pulmonary artery, veins, and bronchus.

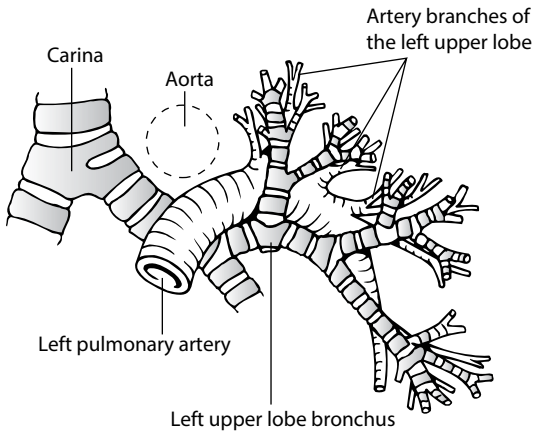

Figure 42.10 Main segmental pulmonary artery branches to the left upper lobe.

ligatures. Clips or stapling devices are suitable if appropriately sized. The bronchial blood supply traveling with the left upper lobe bronchus is likewise identified, controlled, and divided. Attention is then directed to the left upper lobe venous drainage. Again, individual branches are circumferentially dissected and ligated using the same approach as for the arterial circulation (Figure 42.11). The bronchus is then dissected, clamped, and divided. Closure of the bronchial stump with commercial surgical stapling devices is appropriate in older children; however, size and other technical limitations may make this undesirable or impractical in infants. If so, a simple sewn closure is best (Figure 42.12). Air leaks may be identified for suture repair by filling the chest with warm saline coincident with inflation of the residual lobe by the anesthesiologist. The inferior pulmonary ligament should be divided at this time to facilitate expansion of the left lower lobe, or it may be done early in the dissection to facilitate exposure. A tunneled chest tube is placed within the pleural space for drainage, and the wound or port site is closed in anatomical layers using absorbable suture. Postoperatively, the chest tube can be removed when there is no demonstrable air leak and output is minimal.

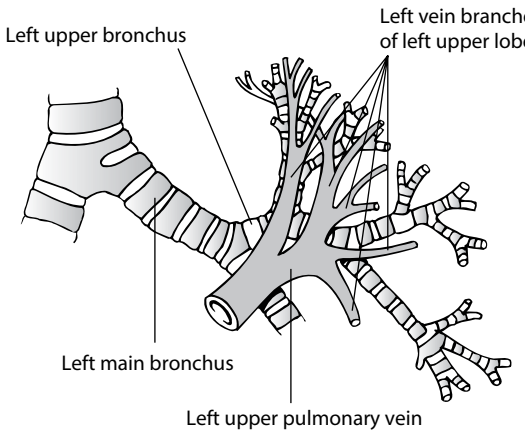

Figure 42.11 Segmental vein branches of the left upper lobe.

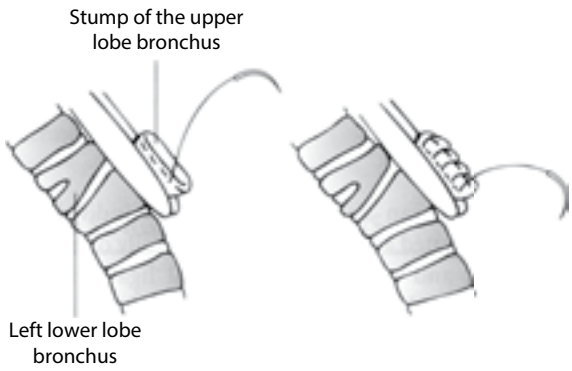

Figure 42.12 Vascular clamp placed across the left upper bronchus and the bronchus oversewn.

Wedge resections and lobectomies are remarkably well tolerated in the pediatric population, although age at resection is a factor. Older children demonstrate less compensatory growth than infants. Even so, most children will have little or no functional deficit after these procedures.[21,22,74]

The need for a pneumonectomy is limited in infants and children. Outcomes of pneumonectomy are generally good, yet children are more likely than adults to develop postpneumonectomy syndrome. This rare and potentially life-threatening complication occurs more frequently in children due to a more mobile mediastinum and greater tissue elasticity.[75] It is characterized by severe mediastinal shift, bronchial stretching, and respiratory failure.[75] Placement of an expandable intrathoracic prosthesis has been described as a strategy to manage this potential problem.[75,76]

Congenital diaphragmatic hernia

PREM PURI AND JULIA ZIMMER

INTRODUCTION

Congenital diaphragmatic hernia (CDH) is a common malformation characterized by a defect in the posterolateral diaphragm, the foramen of Bochdalek, through which the abdominal viscera migrate into the chest during fetal life. Population-based studies have reported the prevalence of CDH to be between 1 in 2500 and 1 in 3000 live births.[1,2] A recent study reported the prevalence of CDH in Europe to be 2.3 per 10,000 births for all cases and 1.6 per 10,000 births for isolated cases.[3] Approximately 80% of the CDH cases are left sided, 15% are right sided, and less than 5% are bilateral.[4,5] The size of the defect varies from small (2 or 3 cm) to vary large, involving most of the hemidiaphragm. The international committee of the Congenital Diaphragmatic Hernia Study Group (CDH Study Group), recently created a standardized four-grade (A to D) reporting system for CDH[6]: *A* defects are completely surrounded by muscle. *B* defects have a small and *C* defects a large portion of the chest wall devoid of diaphragm tissue. *D* defects present with a complete or near-complete absence of the diaphragm. The size of the diaphragmatic defect and also a potential severe cardiac anomaly were shown to worsen the outcome.[6] Despite advances in neonatal resuscitation and intensive care, newborn infants with CDH continue to have high mortality. Current survival rates in population-based studies are around 55%–80%.[4,5,7] Highly specialized centers report up to 90% survival but discount the hidden mortality, mainly in the antenatal period.[8] The high mortality and morbidity in CDH are mainly attributed to pulmonary hypoplasia and persistent pulmonary hypertension.[8–10]

EMBRYOGENESIS

The etiology of CDH is still not clearly understood. Although it is generally considered to be sporadic, there are reports of known chromosomal aberrations and autosomal recessive inheritance of unknown chromosomal origin.[11] The embryogenesis of CDH has been described as a failure of the pleuroperitoneal canals in the posterolateral aspect of the diaphragm to fuse during gestational week 8.[12] Consequently, the abdominal viscera including the liver and bowel migrate into the thorax, which is thought to cause pulmonary hypoplasia by compression of the growing lungs. The pulmonary hypoplasia associated with CDH extends to all aspects of the lung, resulting in fewer alveoli, thickened alveolar walls, increased interstitial tissue, and markedly diminished alveolar air space and gas-exchange area.[12] Parallel to airway changes, pulmonary vasculature is abnormal with a reduced number of vessels, adventitial thickening, medial hyperplasia, and peripheral extension of the muscle layer into the smaller intra-acinary arterioles.[13] The morphology of the CDH lung furthermore has an immature appearance.[12,13] The ipsilateral lung is the most severely affected, but the changes usually extend to the contralateral lung as well.

Experimental studies have suggested that the classical view of embryogenesis of CDH may have to be revised. A toxicological nitrofen model of CDH has shown that abnormalities in the contralateral lung as well as the ipsilateral side are present even before the diaphragm starts to develop.[14] Keijzer et al.[15] proposed the *dual-hit* hypothesis to explain the observations on pulmonary hypoplasia in this model. This hypothesis proposes that the early retardation in lung development that occurs before the development of the diaphragmatic defect is caused by nitrofen, whereas the late-gestational increase in lung hypoplasia is caused by mechanical compression from herniated viscera. Kluth et al.[16] have shown that pleuroperitoneal canals are not wide enough to allow herniation of gut loops in rats. Several groups have shown aberrant gene/protein expression of different growth factors and transcription factors in experimental models as well as in patients with CDH.[17–20] The retinoid signaling pathway and also its downstream target COUP transcription factor 2 (COUP-TFII) have been shown to be disrupted in the nitrofen model of CDH.[21–23] Beurskens et al.[24] reported significantly lower levels of cord retinol and retinol-binding protein in neonates with CDH. Vitamin

A–deficient rats display pulmonary hypoplasia with CDH.[25] Furthermore, the lungs in experimental models of CDH exhibit a response to retinoic acid different from normal lungs.[23,26] Furthermore, prenatal retinoic acid (RA) treatment has been shown to upregulate pulmonary expression levels of genes involved in lung morphogenesis in the nitrofen-induced hypoplastic lung.[27] Although prenatal use of RA has been controversial, these experimental data suggest that prenatal RA treatment may have a therapeutic potential to revert pulmonary hypoplasia associated with CDH.

Knockout models for Wt1,[28] Shh,[29] Slit3,[30] Gli2/Gl3,[31] Gata4/Gata6,[32,33] Fog2,[34] Pdgfrα,[35] COUP-TFII,[36] and retinoic acid receptors (RARs)[37] exhibit diaphragmatic hernia. So far, only mutations of Fog2 and WT1 have been identified in human patients with CDH.[35,38,39]

PATHOPHYSIOLOGY

The onset and severity of symptoms depends on the amount of abdominal viscera in the chest and the degree of pulmonary hypoplasia. Postnatally, the most severely affected babies present with respiratory distress (cyanosis, tachypnea, and sternal recession) at birth. Although the major cause of this is pulmonary hypoplasia, the resulting hypoxia and hypercarbia will result in pulmonary vasoconstriction and pulmonary hypertension. This in turn will cause reversal to right-to-left shunting through the ductus arteriosus and the foramen ovale, and the infant enters a vicious, self-perpetuating cycle.

Several factors have been known to contribute to the severe pulmonary hypertension in CDH. The pulmonary vascular bed is abnormal, with increased muscularization of arterioles in a manner similar to infants with idiopathic persistent pulmonary hypertension of the newborn (PPHN).[13] Increased thickness of the media as well as the adventitia of arteries of all sizes has also been demonstrated.[40] Furthermore, vasoactive substances such as endothelin-1 seem to be increased in infants with CDH. Kobayashi and Puri[41] found increased blood levels of endothelin, as well as increased expression of endothelin-1 in endothelial cells in the pulmonary vasculature. Endothelin-1 causes pulmonary vasoconstriction by binding to the endothelin A (ETA) receptor. The ETA receptor is ubiquitously present in the smooth muscle cells of the pulmonary vasculature,[42] and the increased endothelin-1 levels may thus adversely affect pulmonary vasoconstriction.

Hypoxia and hypercarbia may be further aggravated by a reported immaturity of the surfactant system in experimental animals and infants with CDH.[43] Others could, however, not confirm this deficiency,[44] and it has been postulated that the apparent surfactant deficiency may in fact be secondary to respiratory failure, rather than to a primary deficiency.[45]

Recently, Fleck et al.[46] reported that patients with CDH demonstrate proinflammatory and chemotactic signals in fetal blood at the time of birth. The authors suggested that these molecular signals lead to vascular changes resulting in pulmonary hypertension in these patients.[46]

DIAGNOSIS

CDH can be reliably diagnosed prenatally by ultrasonography at about 20 weeks of gestation. The diaphragm can be visualized, and its absence is indirectly suggested by the intrathoracic presence of abdominal viscera and compression of thoracic organs.[47] An important feature to look for is the presence of the liver in the thorax, if necessary using Doppler of the umbilical vein and hepatic vessels.[47]

Differential diagnosis with other intrathoracic pathologies, including congenital cystic adenomatoid malformation (CCAM), bronchopulmonary sequestration, diaphragmatic eventration, and bronchogenic cyst, needs to be made. It is also of vital importance to exclude the presence of other anomalies, including neural tube defects, cardiac malformations, and chromosomal aberrations A recent study demonstrated the prevalence of additional congenital disorders in 50% of the CDH patients.[48] Chromosomal aberrations are found in 5%–30%, with trisomy 21,18, and 13 as the most common anomalies.[1] Furthermore, the degree of pulmonary hypoplasia should be assessed. The presence of the liver in the chest in left-sided CDH indicates severe pulmonary hypoplasia.[49] The lung-to-head ratio (LHR—the area of the right lung at the level of the four-chamber view divided by the head circumference) has been shown to be a predictable estimation of the degree of pulmonary hypoplasia.[50] Additionally, the fetal lung volume and intrathoracic organs can be stratified by magnetic resonance imaging (MRI).[9]

Postnatally, CDH should be suspected in infants with severe respiratory distress at birth or within the first few hours of life. Physical examination reveals a scaphoid abdomen, an increased anteroposterior diameter of the thorax, and mediastinal shift. Breath sounds are absent on the affected side. Associated congenital anomalies may also be seen or revealed on further examination. The definitive diagnosis is made by plain radiography of the chest and abdomen by demonstration of air-filled loops of the bowel in the chest and a paucity of gas in the abdomen (Figure 43.1a,b). There is a mediastinal shift to the opposite side, and only a small portion of lung may be seen on the ipsilateral side.

TREATMENT

As recommended by the CDH Study Group,[51] nowadays, most centers perform endotracheal intubation and mechanical ventilation directly postnatally in order to perpetuate cardiopulmonary stability and delay the natural progression into severe hypoxemia and hypercapnia.[1] Mask ventilation should be avoided as it will distend the stomach and further compromise respiratory status. A baby with CDH should be sedated and have a nasogastric tube placed to prevent distension of the stomach and bowel. The usage of muscle relaxants should be avoided as part of the gentle ventilation strategy.[7,51]

CDH was previously considered a surgical emergency, where prompt surgery was performed with reduction of the

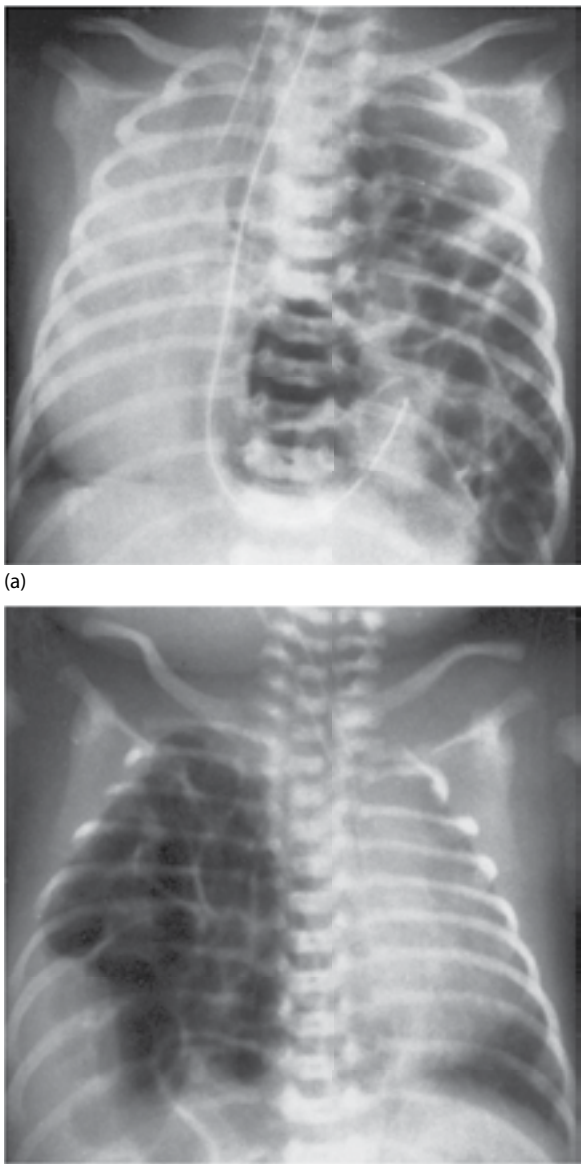

Figure 43.1 **(a)** Left CDH with viscera visible in the left chest, pulmonary hypoplasia, and significant mediastinal shift to the right. **(b)** Right CDH with viscera visible in the right chest and mediastinal shift to the left side.

abdominal viscera, thereby allowing the lungs to expand. The increased knowledge of the pathophysiology of CDH has led to a different approach, where prolonged preoperative stabilization has proven useful. Although it is now usual consensus to wait until the patient is cardiorespiratorily and hemodynamically stable, a Cochrane review provided no clear evidence preferring delayed (when stabilized) or immediate (within 24 hours of birth) surgical hernia repair.[52]

Preoperative treatment

An infant with respiratory distress requires endotracheal ventilatory support. Previously aggressive hyperventilation and hypocarbia were widely used, often causing barotrauma.[53,54] A new approach with gentle ventilation and permissive hypercarbia has been proven to decrease the mortality rate,[55–57] and several centers have shown improved survival as compared to historical controls, using a combination of gentle ventilation and delayed surgery.[53,56]

High-frequency oscillatory ventilation (HFOV) is a valuable tool in the treatment of infants with respiratory distress, since it provides effective ventilation while decreasing barotrauma. However, in CDH, HFOV has not been shown to improve the mortality or morbidity rates.[57–59] The impact of changes in HFOV settings must be monitored carefully, as high airway pressures may cause lung hyperinflation, with adverse effects on venous return, pulmonary vascular resistance, and ultimately cardiac output.[56]

European and American study groups recommend the following initial ventilation settings to achieve a target SaO_2 of >85% preductally and a pCO_2 of 45–60 mmHg.[51,57]

For pressure-controlled ventilation, the setting should comprise a peak inspiratory pressure (PIP) of 20–25 cm H_2O, a positive end-expiratory pressure (PEEP) of 2–5 cm H_2O, and a frequency (f) of 40–60/minute. Using HFOV, the mean airway pressure (MAP) should be 13–17 cm H_2O, with a frequency of 10 Hz and a pressure delta (Δp) of 30–50 cm H_2O, based on the extent of chest rise on the chest x-rays.[51,57]

Nitric oxide (NO) is a direct pulmonary vasodilator, and inhalation (5–20 parts per million) improves oxygenation,[1] but its relevance for CDH patients with CDH remains controversial.[1,60,61] NO can cause a short-term improvement in oxygenation in selected patients, which is beneficial for stabilizing the patient during transport or awaiting the extracorporeal membrane oxygenation (ECMO) cannulation; however, inhaled NO does not reduce the need for ECMO itself.[1,62,63]

ECMO is a life support system used in the treatment of CDH when conventional mechanical ventilation fails. ECMO employs partial heart–lung bypass, providing rest to the lungs for long periods of time, during which it is hoped that the lung and pulmonary vasculature will mature. Several centers advocate the use of ECMO only in patients with evidence of a "honeymoon period," i.e., patients with adequate gas exchange for a period preceding the deterioration in respiratory status. Others use preductal blood gases, where only patients with a period of normal preductal pO_2 and pCO_2 will be considered for ECMO.[56] Although widely used, a Cochrane review found that the ECMO benefit is unclear,[64] and also, other studies were unable to show a survival benefit of ECMO usage in CDH patients.[65,66]

Surfactant replacement has been tried as an adjunct to conventional mechanical ventilation or ECMO, but its administration is not without risk, and the benefits remain unclear.[56,67] Other ventilation strategies have been tried in CDH infants to provide efficient ventilation and protect the lung against barotrauma. Partial liquid ventilation has been shown to be beneficial in some cases, and some preliminary promising results have been obtained by the use

of intratracheal pulmonary ventilation (ITPV).[68] However, none of these methods can improve the fundamental problem with the CDH lung, i.e., hypoplasia, and they therefore share the shortcomings of ECMO treatment.

Appropriate fluid management, as well as the use of inotropic agents, is crucial in the treatment of CDH. Adequate sedation and pain management should be used. Surgery should be performed when the infant is stable with minimal ventilator settings and is diuresing well, and the chest radiograph is improving. Routine administration of prenatal or postnatal glucocorticoids is not recommended.[57]

Several alternative therapies are in use for NO-resistant pulmonary hypertension. The phosphodiesterase inhibitor (PDE) 5 inhibitor sildenafil enhances NO-mediated vasodilatation,[1] and its use has been shown to improve oxygenation and outcome.[69,70] The efficacy of the PDE 3 inhibitor milrinone in neonates has been described in several case reports.[1] Other agents with proposed benefit are prostaglandins or Endothelin-1 (ET1) receptor antagonists, and also, novel agents like L-citrulline, Rho-kinase inhibitors, or proliferator-activated receptor-γ agonists are currently under investigation.[71]

Operative repair

An open approach (laparotomy or thoracotomy) or minimally invasive surgery (laparoscopic or thoracoscopic) is still a matter of discussion for the surgical repair of the diaphragmatic defect[72] (Figure 43.2). The most commonly preferred approach is abdominal, offering good exposure, easy reduction of the abdominal viscera, and recognition and correction of associated gastrointestinal anomalies.[68] The contents of hernia are gently reduced in the abdomen. On the right side, the small intestine and the colon are first reduced, and the liver is withdrawn last. After the hernia is reduced, an attempt is made to visualize the ipsilateral lung. Most diaphragmatic defects can be sutured by direct sutures of the edges of the defect. Although the anterior rim of the diaphragm is usually quite evident, the posterior rim may not be immediately apparent and may require dissection for delineation. There is usually a layer of peritoneum running from the retroperitoneum over the lower edge of the defect. Division of this tissue usually allows visualization of the posterior edge of the diaphragm. The defect is closed by interrupted nonabsorbable suture.

Sometimes, the posterior rim is absent altogether, in which case the anterior rim of the diaphragm is sutured to the lower ribs with either periosteal or pericostal sutures. In some cases, the defect is too large for primary closure, and prosthetic material is used (Figure 43.2f). Various patch types are commercially available (absorbable vs. nonabsorbable, natural vs. synthetic), but the ideal material has not been identified yet.[73]

An alternative is a muscle flap taken from the transversus abdominus, leaving the outer abdominal muscle layers intact. This technique should not be performed on patients on ECMO, or at risk of ECMO treatment, because of the risk of hemorrhagic complications. It also should be noted that the operations involving muscle flaps are too long and complex for critically ill patients and can lead to unsightly chest deformities. If the abdominal cavity is small, gentle stretching of the abdominal wall will enable safe closure in most patients. Whether a chest drain should be inserted prior to closure is controversial. The argument against the use of a chest drain is in avoidance of barotraumas as it increases the transpulmonary pressure gradient.

Minimally invasive surgery has been argued to reduce the trauma and physiological disturbance of surgery and cause a cosmetically better outcome. Although survival and patch usage are similar to open surgery, neonatal thoracoscopic CDH repair has been found to be associated with greater recurrence rates, longer operative times, and severe intraoperative hypercapnia and acidosis.[74–76]

Postoperative treatment

Postoperative care should be performed in the same manner as preoperatively, with a close watch on fluid management, ventilator, support and hemodynamic monitoring.[77] Some infants show improvement in oxygenation in the honeymoon period but usually deteriorate 6–24 hours later. This deterioration is due to pulmonary hypertension and persistent fetal circulation with an increase in pulmonary artery resistance, elevated pulmonary artery pressure, and right-to-left ductal and preductal shunting, leading to hypoxemia. Pulmonary hypertension is probably caused by multiple factors, such as increased abdominal pressure with impaired visceral and peripheral perfusion, limited diaphragmatic excursion, overdistension of the alveoli in the hypoplastic lungs with diminished alveolar-capillary blood flow, release of vasoactive cytokines, and deterioration in pulmonary compliance after surgical repair. Sudden deterioration in the patient's oxygenation status should raise the suspicion of pneumothorax. Infection complications including pneumonia and septicemia are not uncommon.

PRENATAL TREATMENT

A prenatal intervention that can reverse the lung hypoplasia might theoretically improve prognosis. Fetal surgery with primary repair of the defect seemed to be a promising approach, but clinical application of anatomical fetal CDH repair was abandoned once it became clear that it was not possible in fetuses with liver herniation and that those without did not benefit from the intervention.[78,79]

A fetoscopic tracheal occlusion (FETO) was then developed as it became clear from experimental studies that lung growth can also be triggered by tracheal occlusion. The effect on lung growth by tracheal occlusion and retention of pulmonary fluid seems to be exerted by pulmonary stretch itself, which in turn causes upregulation of different growth factors.[80–82] For FETO, currently, a one-port technique with endoscopic placement of a tracheal balloon is used.[50,83] A European group has achieved the best results

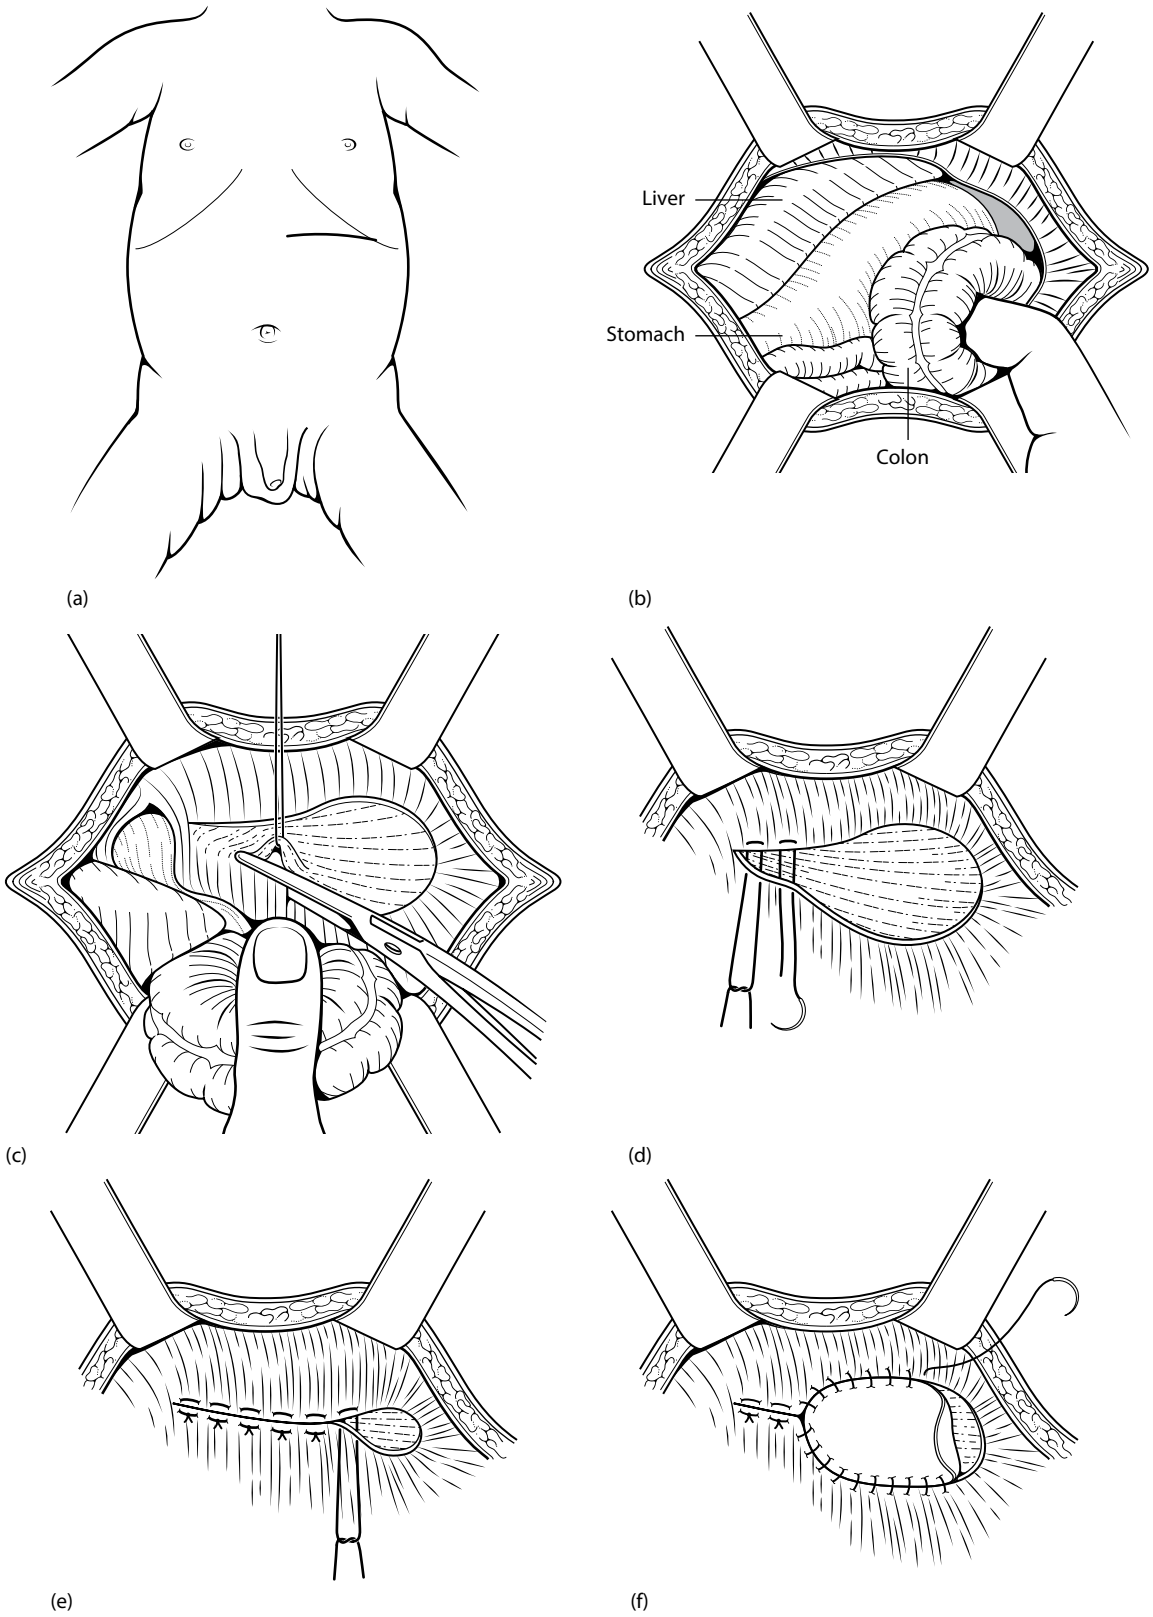

Figure 43.2 Operative repair of CDH. **(a)** A subcostal transverse muscle cutting incision is made on the side of the hernia. **(b)** The contents of hernia are gently reduced in the abdomen. **(c)** After inspecting the diaphragmatic defect, the posterior rim of the diaphragm is mobilized by incising the overlying peritoneum. **(d** and **e)** The defect is then closed by interrupted nonabsorbable sutures. **(f)** Large diaphragmatic defect is closed by using Surgisis soft tissue graft.

using balloon deflation by repeat tracheoscopy at 34 weeks' gestation,[50] permitting vaginal delivery. The most complication of FETO procedure is preterm premature rupture of the membranes (PPROM), which is probably iatrogenic in nature.[84] PPROM does have an impact on gestational age at delivery and complicates balloon removal.[84] In order to deliver infants with FETO, a special method of delivery had to be developed, the ex utero intrapartum treatment procedure (EXIT). Cesarean section is performed with maximal uterine relaxation, and while keeping the infant on placental support, the upper airway can be instrumented. However, a recent Cochrane analysis showed that there is currently only insufficient evidence to recommend in utero intervention for CDH fetuses as a routine clinical practice.[85] Neither an open nor a minimally invasive FETO approach delivered enough suitable data on perinatal mortality. Furthermore, antenatal corticosteroid treatment presented no clear benefit regarding perinatal mortality, days of mechanical ventilation, or days of hospital admission.[85]

Various other medical strategies for lung hypoplasia have been tested in the last decades in different CDH animal models.[9,86] These studies mainly focus on steroid administration with or without thyrotropin releasing hormone, vitamins, and stem cell therapy, but their future value for the human situation has yet to be addressed.[9,86]

PROGNOSIS

It is of vital importance to recognize variables that predict prenatal and perinatal mortality, since they will influence the information given to the family, as well as deciding eligibility for prenatal intervention. Firstly, other lethal malformations, as well as chromosomal aberrations, should be excluded. Intrathoracic herniation of both the liver and the stomach has been shown to be associated with a higher mortality.[9,87,88] The LHR can adequately predict outcome in CDH. LHR values <1 are associated with a worse prognosis with high risk of death, need for ECMO, and pulmonary hypertension at 1 month.[9,89] The observed-to-expected LHR (O/E LHR) is associated with death if the value is less than ~20%.[87] In MRI studies, the observed-to-expected total fetal lung volume (O/E TLV), percent predicted lung volumes (PPLV), and percent liver herniation have been found to correlate with survival, need for ECMO, and development of chronic lung disease.[9,90–92]

Several other factors have also been reported to be predictors for survival. In 2001, the CDH Study Group created a logistic equation using birth weight and 5-minute Apgar score to separate between high, intermediate, and low risk of death.[93] Later, they stratified the fetus risk using the factors very low birth weight, absent or low 5-minute Apgar score, presence of chromosomal or major cardiac anomaly, and suprasystemic pulmonary hypertension.[94]

Initial, $PaCO_2$ in nonsurvivors at 30 days has been found to be higher than the levels in survivors.[1,95] Furthermore, neonates with continuous hypercarbia had a worse prognosis than those who were stabilized to a normal $PaCO_2$.[95] Further biomarkers to predict the patient's outcome are the best oxygenation index on day 1[96] and the simplified formula of postnatal blood gas (PaO_2–$PaCO_2$) to predict the need for ECMO or death.[97] Wynn et al.[8] found that low birth weight, patch repair, and need for ECMO correlate with more severe pulmonary hypertension at 1 month.

LONG-TERM OUTCOME

Improvement in the treatment of infants with CDH has increased the survival of more severely affected infants. Long-term follow up of those patients has led to the recognition of pulmonary and extrapulmonary morbidities that were not previously recognized. Pulmonary morbidity is the most common problem in CDH infants surviving beyond the neonatal period, which is even more distinct in patients treated with ECMO or requiring patch repair.[98] The prevalence of BPD was reported to be 41% in CDH neonates who survived until day 30.[99] Furthermore, the severity of chronic lung disease in CDH survivors may require prolonged ventilator support and tracheostomy.[98,100] CDH survivors also suffer from recurrent respiratory tract infections in infancy and early childhood.[101]

Some authors recommend palivizumab (Synagis) vaccination for CDH infants in the fall and winter.[102–104] However, there are currently no large clinical studies investigating the efficacy of palivizumab in depleting hospitalization rates for respiratory tract infections in these patients.[101]

Neurodevelopmental abnormalities have been abundantly described in CDH survivors presenting developmental delay; motor, cognitive, and behavioral disorders; as well as impaired language and neurocognitive skills.[101,105–107]

Sensorineural hearing loss (SNHL) has also been frequently reported in CDH survivors.[101] Potential predisposing factors, including the use of ototoxic medications and prolonged mechanical ventilations with high oxygen tensions, lead to SNH, which is found in CDH survivors treated with or without ECMO, suggesting that the use of ECMO is not the only predisposing factor for SNHL.[108] However, several retrospective studies found that the SNHL rate in both ECMO and non-ECMO CDH survivors is between 2.3% and 7.5%,[109–111] which is equivalent to the SNHL rate of all neonatal intensive care unit patients.[101,112]

A significant number of CDH survivors present gastrointestinal symptoms, including gastroesophageal reflux (GER), failure to thrive (defined as weight < 25th or 5th centile), and late bowel obstruction.[113,114] Gastrostomy tubes needed to be placed in one-third of patients in two survival cohorts due to nutritional morbidity.[101,115,116] Gastroesophageal reflux disease (GERD) treatment usually starts with H2-blockers, but if clinical problems like pulmonary infections or choking persist, fundoplication should be considered.[101] Nearly 40% of babies operated on for CDH will have symptomatic GER, half of which require antireflux surgery.[117] The most frequently reported predictor of antireflux surgery is the need of diaphragmatic patch repair.[98,116] Recurrence is more common in patients repaired

with a prosthetic patch. Additionally, patients with patch repair have a higher risk for developing musculoskeletal deformities such as pectus excavatum or scoliosis.[118]

Although most survivors beyond the neonatal period are able to lead a normal life, children with CDH should be multidisciplinarily followed up and assessed for their pulmonary, neurodevelopmental, and nutritive outcome until adolescence.

CONGENITAL EVENTRATION OF THE DIAPHRAGM

Eventration of the diaphragm characterizes an atypically high or deviated position of all or parts of the hemidiaphragm, which can occur congenitally or be acquired as a result of phrenic nerve palsy. Congenital eventration is a developmental abnormality leading to muscular aplasia of the diaphragm, which primarily has fully developed musculature and becomes atrophic secondary to phrenic nerve damage and disuse. The incidence of congenital eventration of the diaphragm (CDE) is 1 per 1400 patients, with higher prevalence in males.[119] This paragraph deals with congenital eventration; however, clinical characteristics and management strategies are similar in congenital and acquired forms of eventration.

Clinical characteristics

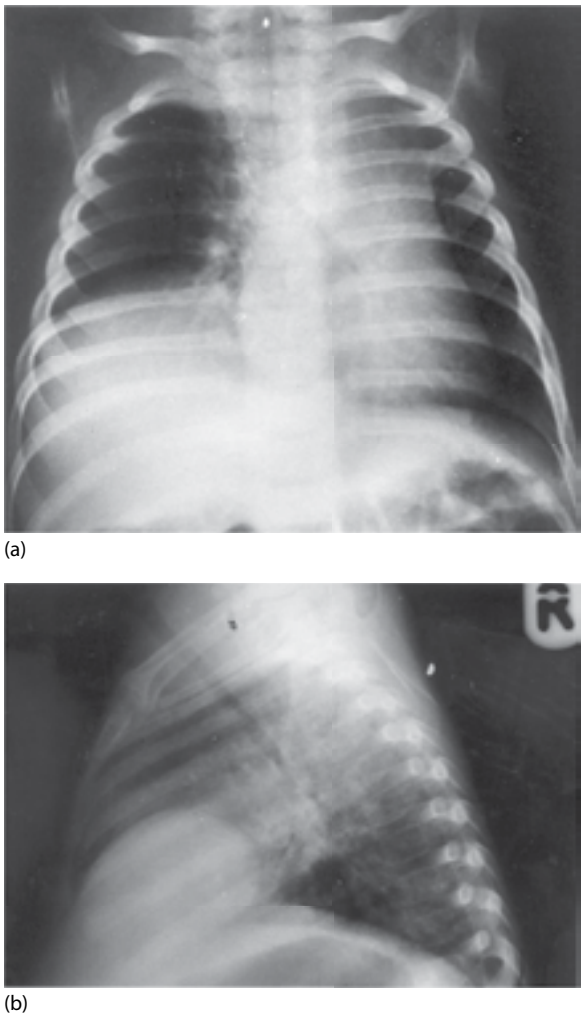
Clinical characteristics of CDE vary widely from being asymptomatic to severe respiratory distress, bronchitis, pneumonia, or bronchiectasis. Gastrointestinal symptoms like vomiting or epigastric discomfort are also reported in later childhood. Patients with phrenic nerve palsy may have a history of difficult delivery, exhibiting tachypnea, respiratory distress, or cyanosis. During physical examination, breathing sounds may be reduced on the affected side, and a mediastinal shift during inspiration and a scaphoid abdomen are observed. Occasionally, CDE patients present with associated malformations such as hypoplastic lung, congenital heart disease, or cryptorchidism.[119]

Diagnosis

CDE is usually diagnosed via chest x-ray, revealing an elevated diaphragm with a smooth, unbroken outline on frontal and lateral chest x-rays (Figure 43.3a,b). Fluoroscopy is useful to distinguish a complete eventration from a hernia. Complete eventration can lead to paradoxical diaphragmatic movements. Ultrasound is the most useful tool in diagnosing CDE and to identify abnormal organs underneath the eventration. Other study modalities such as pneumoperitonography, contrast peritonography, radioisotope scanning, and computed tomography (CT) or MRI scans are rarely required.

Management

Asymptomatic patients without crucial pulmonary abnormalities may be treated observantly. Likewise, conservative



(a)

(b)

Figure 43.3 **(a)** Anterior-posterior (AP) x-ray image showing right CDE with liver visible in the right chest and mediastinal shift to the left. **(b)** Lateral x-ray image of right CDE with liver visible in the right chest.

treatment is recommended for patients with incomplete phrenic nerve palsy without paradoxical movement as normal function usually returns.

In contrast, symptomatic patients, especially those with respiratory distress, need prompt respiratory support and ventilation with humidified oxygen to minimize the diaphragmatic excursions. Intravenous fluids should be started, and a nasogastric tube helps to decompress the stomach. Surgery is undertaken once the patient's condition is stabilized.

Operative repair

Diaphragmatic plication is the method of choice, increasing both tidal volume and maximal breathing capacity (Figure 43.4). An abdominal approach trough a subcostal incision is useful for left-sided CDE. A thoracic approach with a posterolateral incision in the sixth space may be used for right-sided CDE. A transabdominal approach facilitates good visualization of the complete diaphragm and easier mobilization of

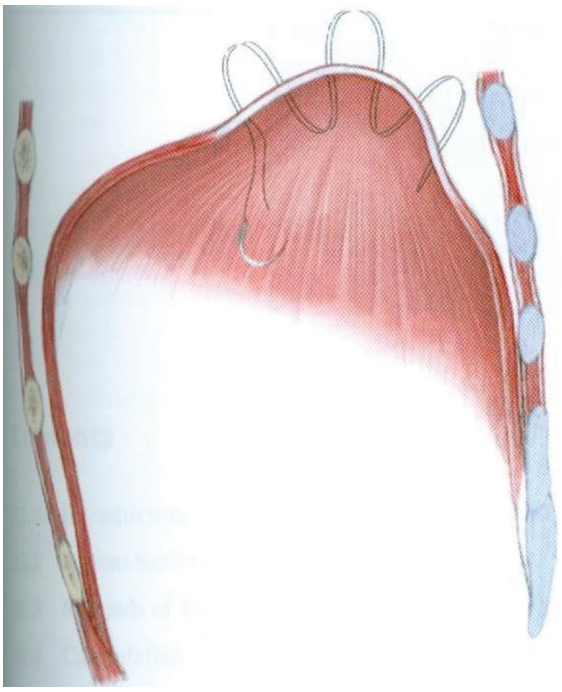


Figure 43.4 Plication repair of diaphragmatic eventration.

abdominal contents. Plications via laparoscopic and thoracoscopic approaches are also safe repair methods.

Outcome

Patients with CDE without underlying pulmonary hypoplasia commonly have an excellent prognosis. Mortality is related to pulmonary hypoplasia. A recent large single-center study showed that timely precise diagnosis and management of symptomatic CDE effectively prevents respiratory morbidity and diminishes complications,[119] including recurrence, renal insufficiency, as well as pneumonia and pleural effusions.[119]

Extracorporeal life support for neonatal cardiorespiratory failure

WILLIAM MIDDLESWORTH, JEFFREY W. GANDER, AND CHARLES J. H. STOLAR

INTRODUCTION

Extracorporeal membrane oxygenation (ECMO) is a life-saving technology that temporarily replaces the function of the heart and lungs. It is a supportive modality rather than a therapeutic tool that provides gas exchange and mechanical hemodynamic support for neonates with an acute, reversible respiratory or cardiac condition. This support spares the infant from the deleterious effects of high Fi02, high airway pressure, traumatic mechanical ventilation, and perfusion impairment. ECMO was first used in newborns in 1974. Since then, the Extracorporeal Life Support Organization (ELSO) has recorded approximately 36,000 newborns that have been supported with ECMO for a variety of cardiorespiratory disorders. The most common disorders in the newborn treated with ECMO are meconium aspiration syndrome (MAS), persistent pulmonary hypertension of the neonate (PPHN), congenital diaphragmatic hernia (CDH), sepsis, and cardiac support. Depending on the indication for ECMO, the outcome is varied, but overall, a cumulative survival rate of over 80% has been reported for newborns (reported to the ELSO registry since its inception) treated for respiratory failure.[1] This chapter will discuss the selection criteria for ECMO in neonates and the management of these babies while on ECMO. It will then discuss ECMO for use in difficult clinical scenarios, such as CDH, and finally review outcome and follow-up of neonates treated with ECMO.

SELECTION CRITERIA FOR NEONATAL ECMO

The selection criteria for newborns are based on historic experience from multiple institutions, patient safety, and mechanical limitations related to the biomedical devices.

Gestational age

The gestational age should be at least 34 weeks. In the early experience with ECMO, infants <34 weeks' gestation who were offered ECMO developed significant morbidity and mortality related to intracranial hemorrhage (ICH).[2] Despite refinement of ECMO techniques in the ensuing decades, premature infants continue to be at high risk for ICH. This may be due to inherent fragility of the germinal matrix vasculature of the premature infant's developing brain, making them susceptible to intracranial bleeding.[3] The incidence of ICH decreases with advancing gestational age. Hardart et al.[4] reported a 22% incidence of ICH at 32 weeks versus 12% at 36 weeks gestational age. The systemic anticoagulation necessary to maintain a thrombus-free ECMO circuit also increases the risk and severity of bleeding complications.

Birth weight

The birth weight should be nearly 2000 g, as children under this weight present unique anatomical challenges to cannulation. The smallest single-lumen ECMO cannula is 8 French (Fr.), and the vessels of very small infants may not accommodate commercially available cannulas. Furthermore, the radius of a tube greatly impacts flow. Poiseuille's law tells us that flow through a tube is related to the fourth power of the radius of the tube. If the vein is small, then the cannula will be small, resulting in flow that will be reduced by a fourth power. From historic experience, if the baby weighs less than 2 kg, then the difficulty of the placement of the cannulas in conjunction with the inadequate flow from small catheters makes ECMO in these small babies challenging.

Bleeding and coagulopathy

Active bleeding and major coagulopathy represent relative contraindications to ECMO support. Patients with uncorrectable coagulopathy, ongoing uncontrollable bleeding, or sepsis are at high risk of bleeding complications while on ECMO. The need for continuous systemic heparin therapy adds to this risk of bleeding.[4] Therefore, prior to initiating ECMO, bleeding should be controlled and coagulopathy should be corrected whenever possible.[5]

Preexisting intracranial hemorrhage

The infant should not have an ICH. Preexisting ICH may be exacerbated by the use of heparin and the altered cerebral blood flow while on ECMO. Infants with small interventricular hemorrhages (grade I–II) may be considered for ECMO on an individual case basis, but these patients should be closely monitored for worsening bleeding. Patients with previous intracranial bleeds, cerebral infarcts, and other risk factors (prematurity, coagulopathy, ischemic central nervous system injury, or sepsis) are particularly at high risk for severe neurologic consequences.[2,6] Discussion with parents in this circumstance, prior to cannulation, is especially important.

Reversible disease process

ECMO support is best suited to infants with reversible or transient cardiorespiratory failure. Ideally, ECMO candidates will have been supported by invasive mechanical ventilation for no longer than 10–14 days. Babies who have had prolonged exposure to high inspired oxygen concentration and positive-pressure ventilation develop bronchopulmonary dysplasia (BPD).[7] Recovery from this type of irreversible lung injury may take from weeks to months to occur, if it does at all. Support with ECMO can be beneficial for reversible lung disease over a relatively short period of time (2–3 weeks). However, even a lengthy ECMO course is unlikely to be sufficient to permit recovery of the irreversible fibrotic changes that occur to the lung following sustained barotrauma and/or oxygen toxicity. In addition, with a longer ECMO run, the chance of infection, bleeding complications, thromboembolic events, and mechanical failure increases.

In a retrospective case–control study, which reviewed the records of ECMO patients over 66 months, patients with oxygen dependency at 1 month of age and radiographic evidence of BPD were compared to patients without these findings.[8] Patients with BPD were placed on ECMO at an older mean age than non-BPD patients (135 versus 50 hours old). The BPD group had longer mean ECMO courses as well (203 versus 122 hours). The authors suggest that BPD from high levels of ventilatory support can occur with as few as 4 days of assisted ventilation.

ECMO is used with increasing frequency and success to support infants who develop myocardial dysfunction and hemodynamic instability in the period surrounding repair of congenital heart disease.[9] The transient myocardial dysfunction that is sometimes seen in the post cardiotomy period is an example of a reversible process well suited to ECMO support.

Coexisting anomalies

ECMO is not intended to prolong the process of an inevitable death, and therefore, candidates should have no lethal congenital or chromosomal anomalies such as trisomy 13 or 18. Other treatable conditions, such as total anomalous pulmonary venous return (TAPVR) and transposition of the great vessels (TOGV), may initially manifest with cardiorespiratory failure. When possible, an echocardiogram should be rapidly obtained to determine whether ECMO or surgical correction is most appropriate.

Bridge to diagnosis

Every effort should be made to establish a clear diagnosis before the initiation of ECMO. Circumstances arise, however, where clinical decompensation is rapid, and survival depends on immediate provision of mechanical hemodynamic support. In this situation, it is reasonable and appropriate to institute ECMO, with a plan to establish the diagnosis after achieving clinical stability during the course of ECMO. For example, pulmonary vein misalignment, a uniformly fatal anomaly of deficient alveolar capillaries and anomalous veins within the bronchoarterial bundles, presents with symptoms of persistent pulmonary hypertension unresponsive to pharmacologic treatment.[10] These infants are often placed onto ECMO. When pulmonary hypertension is intractable despite ECMO support, the diagnosis of alveolar capillary dysplasia should be entertained.[11] This diagnosis is made via lung biopsy. If alveolar capillary dysplasia is confirmed, then discussion with the family regarding withdrawal of ECMO support is appropriate. In addition, some important cardiac conditions such as TAPVR and TOGV with intact septum may present as respiratory failure, as mentioned previously. These patients are occasionally placed onto ECMO before an accurate diagnosis can be rendered. Once the diagnosis is established, appropriate treatment should be instituted.

Failure of medical management

Before institution of ECMO support, all medical means of managing cardiopulmonary failure should have been attempted. The precise definition of "failure of optimal medical management" is a subjective term, whose definition may vary among institutions. Different institutions have varying specialties, capabilities, and expertise. Current optimal medical management generally includes pharmacologic support with vasodilator or vasoconstrictive agents, inotropic agents, sedatives and analgesics, and correction of treatable conditions like pneumothorax. Ventilatory support usually begins with noninvasive and conventional invasive strategies, but

may escalate to include exogenous surfactant administration, inhaled nitric oxide, or high-frequency oscillatory ventilation. The merits and drawbacks of these treatment strategies are beyond the scope of this chapter. While the concept may be difficult to quantify, a team of involved clinicians can usually reach consensus about when further medical treatment is unlikely to reverse clinical deterioration.

Innovations in medical management have obviated the need for ECMO in patients who, historically, would have required it. These innovations include high-frequency oscillatory ventilation, permissive hypercapnea with spontaneous ventilation, and nitric oxide. In 1985, Wung et al.[12] used a nontraditional approach to the management of patients with persistent pulmonary hypertension. Hyperventilation and hyperoxia were *not* emphasized, and muscle relaxants were *not* used. Permissive hypercapnea in conjunction with spontaneous ventilation was employed. In the reported series of 15 patients, a $PaCO_2$ of 50–80 mmHg and a PaO_2 of 40 mmHg were tolerated, and the minimal inspiratory pressure that provided adequate chest wall excursion was used. These patients, who otherwise met institutional criteria for ECMO, survived with this medical approach alone.

Other, more objective criteria have been established to quantify respiratory failure and aid in determining which infants should be placed on ECMO. High ventilator settings (PIP > 40 cm H_2O, PEEP > 7 cm H_2O, IMV > 100, and FiO_2 of 1.0) have correlated with mortality. In addition, other studies have identified arterial oxygen pressure (PaO_2 < 40 mmHg), alveolar–arterial oxygen gradient (A-aDO_2 > 625 mmHg for 4 hours), and oxygenation index (OI > 40) as predictors of mortality.[13–16] Some investigators have argued that the alveolar–arterial oxygenation gradient and oxygenation index should not be heavily weighted as indicators to implement ECMO support because they can be manipulated by altering ventilator settings.

CLINICAL MANAGEMENT OF NEONATES ON ECMO

Venovenous versus venoarterial ECMO

Venoarterial (VA) ECMO involves drainage of venous blood from the infant (typically from the right atrium, through a cannula placed in the right internal jugular vein) and return of oxygenated blood into the aorta (typically through a cannula placed in the right common carotid artery). This mode augments or replaces the function of both the heart and lungs. For infants with respiratory failure but preserved hemodynamics, venovenous (VV) ECMO support may be appropriate. VV ECMO is most often delivered through a dual lumen cannula directed into the right atrium through the right internal jugular vein. Venous blood is drained from the atrium to the circuit, and the oxygenated blood is returned to the atrium, with flow directed toward the tricuspid valve in an attempt to avoid mixing and recirculation through the circuit. Though cannula design is intended to minimize recirculation, cardiac output is the greatest determinant, and poor cardiac function will cause the recirculation of oxygenated blood through the ECMO circuit, diminishing the delivery of oxygenated blood to the patient. Bicaval dual lumen cannulas are used extensively in adults and older children. These cannulas are positioned across the right atrium into the inferior vena cava, and blood is drained from the superior vena cava (SVC) and the inferior vena cava (IVC) and returned to the atrium, reducing recirculation. In infants, however, the rate of atrial perforation related to bicaval cannula use is considered by some practitioners to be unacceptably high,[17] and so dual lumen atrial, rather than bicaval, cannulas are preferred (Figure 44.1).

In distinction to VV ECMO, VA ECMO provides both respiratory and mechanical hemodynamic supports. It is the preferred mode of support when ECMO is instituted in the setting of cardiac arrest. VA ECMO is also useful in the event of progressive cardiac dysfunction and difficulty weaning from cardiopulmonary bypass after heart surgery, and when decompensation occurs following repair of congenital heart defects. In summary, VV ECMO provides respiratory support, is dependent on native cardiac output to avoid recirculation through the circuit, and does not involve carotid artery ligation. Oxygenated blood is directed toward the pulmonary circulation, which may be therapeutic in treating primary or secondary pulmonary artery hypertension. VA ECMO provides both cardiac and respiratory support, and delivers oxygenated blood more reliably to the systemic circulation. VA ECMO does, however, involve ligation of the right common carotid artery, decreases pulmonary blood flow, and increases left ventricular afterload. When instituting ECMO support, it is always critical to consider native cardiac anatomy and the potential effects of extracorporeal circulation, as certain congenital abnormalities may preclude certain kinds of support (VA

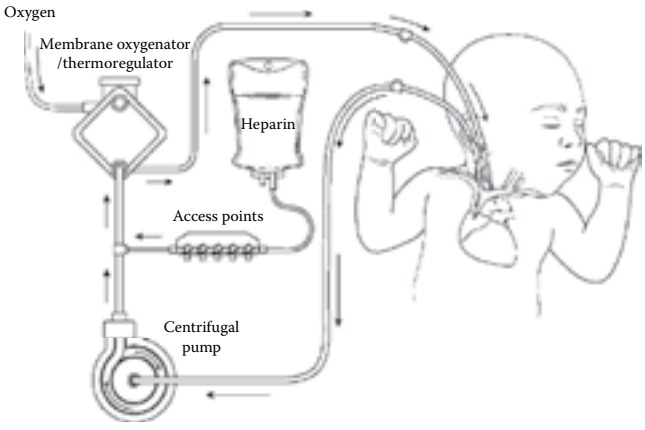

Figure 44.1 Schematic of completed VA ECMO circuit. Extrathoracic cannulation of the right atrium and ascending aorta allows venous drainage to a pump and arterial return directly to the heart and brain. A membrane oxygenator provides oxygenation and CO_2 removal. The blood is temperature-controlled before returning to the infant. All parenterally administered substances such as heparin, fluids, blood products, and drugs can be given directly into the circuit.

ECMO may be contraindicated, for example, in severe aortic coarctation).

Patient preparation and cannulation

The preferred site for cannula placement in an infant is in the vessels of the right neck, as the femoral vessels are too diminutive. The infant is positioned over a transverse shoulder roll with the head at the edge of the bed and turned to the left. After standard preparation of the skin and placement of sterile drapes, cannulation is achieved through open, percutaneous, or combined technique. For VV ECMO, the right internal jugular vein is accessed and the cannula is passed into the right atrium. Portable ultrasound, echocardiography, and x-ray are all useful tools in directing and confirming cannula placement. Percutaneous technique is thought to be associated with preserved vessel patency after decannulation, whereas open technique involves ligation of the vein cephalad to the venotomy. Surgical exposure of the carotid artery and jugular vein is performed to institute VA ECMO support. Adequate anesthetic support is essential. Heparin is administered after identification of the vessels and prior to cannulation. During the open procedure, muscle relaxants are given to prevent the inadvertent aspiration of air into the vein. After placement of the cannulas, they are de-bubbled, flushed, and connected to the circuit. ECMO flow is initiated, and the catheters are carefully secured with sutures to the blood vessel and skin (Figure 44.2a–c).

A chest radiograph is performed to demonstrate cannula position. The tip of the venous cannula should be within the right atrium, while the tip of the arterial cannula should be in the ascending aorta. Echocardiography is used to confirm that the flow of oxygenated blood is toward the tricuspid valve (for VV cannulations) and that the tip of the arterial cannula is cephalad to, and not impinging on, the aortic valve (for VA cannulations).

The ECMO circuit

ECMO circuits have several essential components. Among them are tubing, a pump, an oxygenator, and a heat exchanger that regulates the temperature of the blood as it passes through the circuit. In addition, there are several monitors on the circuit to confirm function and enhance safety. These include pressure and temperature monitors, flow probes to measure blood flow, an oxygen saturation monitor, and a bubble detector. Technological improvements in all circuit components are ongoing and beyond the scope of this chapter, but a general description of them is provided here.

PRIMING THE CIRCUIT

The tubing of the ECMO circuit is initially flushed with crystalloid and purged of all air bubbles. Twenty-five percent albumin solution is then added to coat the tubing, in an attempt to mitigate the inflammatory response that can be provoked by contact of the patient's blood with the tubing. Depending on the priming volume of an individual circuit, approximately 2 units of packed red blood cells are required for initial priming, which displaces the crystalloid and colloid in the circuit. Calcium is added to bring the calcium concentration of the circuit into the physiologic range. Perturbation of serum calcium can provoke arrhythmias during institution of ECMO support. Sodium bicarbonate and heparin are added to the circuit as well to bring pH, oxygen content, and carbon dioxide content of the circuit into the physiologic range. The heat exchanger warms the prime to normal body temperature. In sum, the primed circuit should be as

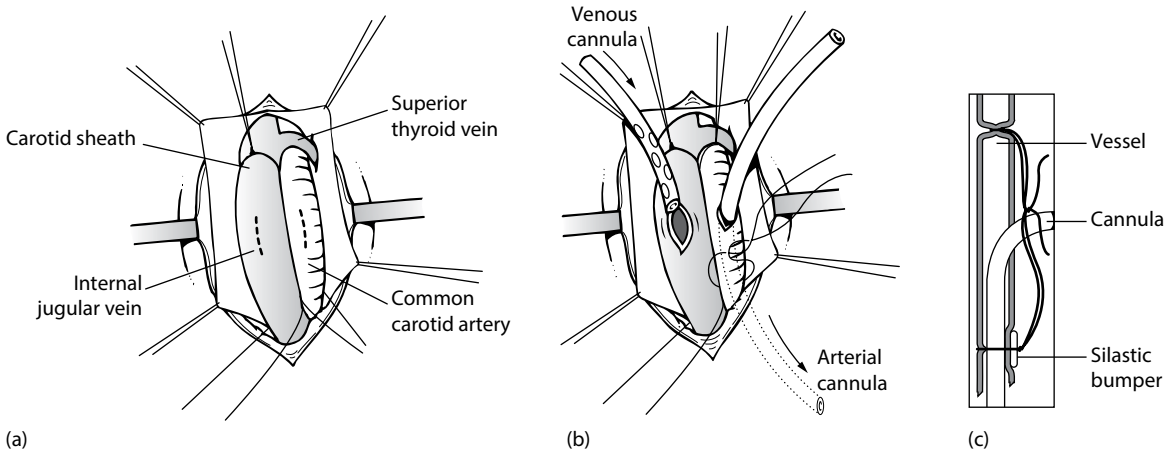

Figure 44.2 Details of the cannulation procedure for VA ECMO. **(a)** The carotid sheath is opened with the sternocleidomastoid muscle retracted. This exposes the common carotid artery and internal jugular vein. **(b)** The infant is anticoagulated after the vessels are dissected and controlled. The vessels are then ligated at the cephalad aspect. An arterial cannula is passed into the aorta through an arteriotomy in the carotid. A venous cannula is passed into the right atrium through the venotomy. **(c)** The cannulas are fixed in position by ligation over a Silastic bumper, de-bubbled and connected to the ECMO circuit. After the incision is closed, the cannulas are also sutured to the skin over the mastoid process.

physiologically normal as possible prior to initiating ECMO to maximize support and minimize metabolic derangement.

PUMP MANAGEMENT

The goal of ECMO is to provide, through augmented flow of oxygenated blood, the oxygen delivery needed to maintain organ function in the critically ill newborn. The pump regulates the flow of blood through the circuit. There are two basic pump configurations in use: roller pumps and centrifugal pumps. Blood flow through a roller pump is directly proportional to the speed, in rotations per minute (rpm) of the roller head as it propels the blood along the "raceway" (tubing within the roller pump housing). Centrifugal pumps, in distinction to roller pumps, contain an impeller that is magnetically coupled to a motor. As the impeller spins, a pressure differential is generated that draws blood through the pump. An important difference between the two types of pumps is that, while flow through a roller pump is proportional to the rpm of the roller head, the pressures at the inlet and outlet of the pump affect flow through a centrifugal pump. The flow driven by the pump should be adjusted to maintain adequate oxygen delivery. Confirmation of adequate oxygen delivery is achieved through standard means: monitoring pH, arterial lactate, urine output, hepatic and renal function, and mixed venous oxygen saturation. It is important to note that, when VV ECMO is used, the blood drawn from the venous limb of a dual lumen cannula may contain recirculated, oxygenated blood being delivered into the right atrium through the arterial limb. This will result in a measured mixed venous saturation that is artificially elevated and not truly reflective of the infant's mixed venous saturation. This is not a concern with VA support when cardiac anatomy is normal.

OXYGENATOR MANAGEMENT

The development of the original bubble oxygenator made open heart surgery possible, but caused too much damage to red blood cells and could therefore not provide support for an extended period of time. Prolonged extracorporeal support was made possible by the development of the membrane oxygenator, where blood was separated from gas by a semipermeable membrane, allowing diffusion of oxygen and carbon dioxide between the gas and the blood, mimicking the function of the human lung. Blood and gas (called "sweep gas") both flow across the oxygenator without coming into direct contact. The oxygen content and flow rate of the sweep gas are adjusted to meet the needs of the patient. Increasing gas flow enhances elimination of carbon dioxide from the blood (at a given blood flow rate), while increasing the oxygen content of the sweep gas enhances oxygenation. More recent and technologically advanced oxygenators (like the poly-methyl pentene hollow-fiber oxygenator currently in use) require lower prime volume, have less leakage of plasma across the membrane and reduced resistance to blood flow. Current oxygenators remain imperfect, however, and thrombus may form in the oxygenator over time. As a thrombus extends, the membrane surface area is decreased, resulting in decreased oxygen and carbon dioxide transfer. Oxygenator function is monitored through the use of pre- and post-oxygenator pressure measurements. An increase in the pressure drop across the oxygenator, or ΔP, may herald oxygenator failure. To optimize performance, blood flow across the oxygenator should be maintained within the parameters suggested by the manufacturer. Pre- and post-oxygenator blood gas analysis is also tracked to monitor oxygenator function. The sweep gas is periodically purged to maintain clear flow across the gas phase of the oxygenator. Extended use during long ECMO runs may result in leakage of blood and plasma across into the gas phase. When evidence of oxygenator failure develops, the oxygenator can be replaced. Experienced ECMO teams are able to cut away and replace a failing oxygenator with a new, pre-primed oxygenator very rapidly. Ventilator and hemodynamic support is transiently escalated during the oxygenator change to support the patient through the brief interruption of ECMO.

Fluid management

Principles and goals of hemodynamic support do not differ substantially during ECMO. While on ECMO, maintenance fluid requirements for a term newborn under a radiant warmer are estimated to be 100 cc/kg/day. Daily insensible water loss through the oxygenator is related to the flow rate of the sweep gas and has been demonstrated by multiple authors in experimental models to be between 50 and 100 mL per liter per minute of sweep. Fluid losses from urine, stool, chest tubes, nasogastric tubes, ostomies, mechanical ventilation, radiant fluid loss, and blood sampling should be carefully recorded. Fluid management may be challenging early in the ECMO course, when capillary leak might occur. Fluid boluses are frequently needed in this period to maintain intravascular volume and circuit function. Meticulous recordings of the net fluid balance on ECMO should be maintained. Typically, there is positive fluid balance and weight gain in the first 1–3 days as the patient becomes increasingly edematous. On the third day of ECMO, spontaneous diuresis of the excess edema fluid frequently begins and can be facilitated with the use of furosemide. This diuretic phase is often a harbinger of recovery. In the event of renal failure on ECMO, hemofiltration or hemodialysis can be added to the ECMO circuit for removal of excess fluid and electrolyte correction. In a retrospective comparison of neonates on ECMO, use of hemofiltration was associated with shorter duration on ECMO and time on mechanical ventilation.[18]

Respiratory management on ECMO

Once the desired oxygen delivery is attained, the ventilator should be promptly weaned in order to avoid oxygen toxicity and barotrauma. Such "rest settings" have been studied and debated.[19] At the authors' institution, the FiO_2 is decreased to 0.21, PEEP to 5 cm H_2O, PIP to 20–25 cm H_2O, a rate of 12 breaths/minute, and inspiratory time of 0.5 seconds provided the infant's arterial and venous oxygenation are adequate.

If a baby remains hypoxic despite maximal pump flow, then higher ventilator settings may be temporarily required. Alternatively, neonates whose hypoxia is not correctible by VV ECMO may need to be converted to VA ECMO to achieve full and adequate cardiorespiratory support. On occasion, the chest x-ray will worsen in the first 24 hours, independent of ventilator settings, and will often improve after diuresis. As the patient improves on ECMO and the pump flow is weaned, ventilator settings are then modestly increased to support the baby off ECMO. In neonates, if the oxygen saturation is greater than 93%, the authors consider FiO_2 of 0.4, PIP < 28, PEEP of 5, and a respiratory rate of <30 breaths/minute as adequate settings for a trial off of ECMO.

During the course of ECMO, pulmonary toilet is essential to respiratory improvement and includes gentle chest percussion and postural drainage. Special attention should be made to the ECMO catheters and keeping the head and body aligned. Endotracheal suctioning is also recommended every 4 hours and as needed based on the amount of pulmonary secretions present.

Medical management

After the initiation of ECMO, vasoactive medications should be weaned and discontinued, provided the blood pressure remains stable. With VV support, improved oxygenation often results in improved cardiac function, and with VA support, the mechanical blood pressure support replaces pharmacologic agents. At the authors' institution, routine consultation from the neurology service and electroencephalography (EEG) monitoring are employed, as seizure activity in newborns is clinically evident only one third of the time.[19] When detected, seizures are treated with standard antiepileptic medication. Both cranial ultrasound and chest radiograph are obtained daily. Nasogastric decompression is maintained, and stress ulcer prophylaxis with an H_2-blocker is instituted. Fentanyl and midazolam are usually administered for analgesia and sedation; however, the use of paralytics is avoided. The baby's muscle activity is important not only for fluid mobilization of edema but also for monitoring of neurologic activity.

As is the case for all patients with central vascular catheters, infection is a constant concern; therefore, strict observance to aseptic technique when handling the ECMO circuit should be maintained. Routine blood, urine, and tracheal cultures are obtained to monitor for infection. At our center, infectious prophylaxis is provided by cefazolin, if antibiotics are not being given for specific treatment; many neonates who are placed on ECMO are already receiving broad-spectrum antibiotics at the time of cannulation.

The caloric intake on ECMO should be optimized using standard hyperalimentation. For a newborn, total parenteral nutrition (TPN) should be started at 100 kcal/kg/day. Normally, this should be supplied as 60% carbohydrates (14.6 g/kg/day) and 40% fat (4.3 g/kg/day). Intralipid infusions may be used as a fat source, although there is some controversy with its use in the setting of severe lung disease. As a result, the percentage of fat in the hyperalimentation may be lowered. Amino acids are provided, with consideration given to impaired kidney function. With normal renal function, approximately 2.5 g protein/kg/day should be provided in the TPN mixture.

The benefits of enteral nutrition are increasingly recognized, and consensus guidelines support the use of enteral nutrition in newborns on ECMO support whose condition has stabilized.[20] Initial concern with feeding enterally on ECMO was that there was inadequate gut perfusion from the initial insult, which could lead to necrotizing enterocolitis when feeding was begun.[21] However, a retrospective study of 67 neonates supported with VA ECMO that were fed enterally did not show any significant adverse effects.[22] While septic complications of enteral feeding are infrequent, many of these patients will have a gastrointestinal ileus. Of the previously mentioned 67 neonates, 21% had enteral feeding temporarily discontinued due to high gastric residuals.

Electrolytes are closely monitored and repleted as necessary. Sodium and phosphorus are usually not repleted as they are often provided in blood products and volume expanders.

Coagulation management

Guidelines regarding the management of anticoagulation are institution-specific, and the intricacies of caring for complex ECMO patients have hindered widespread acceptance of any one specific protocol. At the authors' institution, a guideline for management of anticoagulation is developed for ECMO patients that have "bleeding" and "nonbleeding" arms to recognize the special circumstances involved when caring for an ECMO patient with active hemorrhage. Additionally, special care must be exercised in managing anticoagulation in the perioperative period, such as when a patient with CDH is repaired while on ECMO. Agents such as aminocaproic acid, which binds plasmin and inhibits fibrinolysis, are useful in this setting.

As noted previously, a heparin bolus of 50–100 units/kg is administered at the time of cannulation. When the activated clotting time (ACT) falls below 300 seconds, a continuous heparin infusion is begun at a dose of 28 units/kg/h and titrated to a goal heparin level (antifactor Xa assay) of 0.3–0.7 U/mL, which typically corresponds to an activated partial thromboplastin time (aPTT) of 60–80 seconds. Other useful parameters are the international normalized ratio (INR), prothrombin time, fibrinogen, and the antithrombin III (ATIII) level. Our practice is to maintain the INR at less than 1.5 with transfusion of fresh frozen plasma. Recombinant ATIII is administered to maintain the ATIII level above 50%, and cryoprecipitate is transfused (5 mL/kg) to keep the fibrinogen level greater than 150 mg/dL. While on ECMO, the baby's hemoglobin is maintained above 12 g/dL to maximize the oxygen-carrying capacity of the blood. Platelet consumption is commonly seen during

ECMO, and platelet transfusion is given to maintain a platelet count above 80,000/mm.[23] Point-of-care monitoring of anticoagulation is sometimes necessary when laboratory processing times do not meet clinical needs, and the ACT is useful in this setting. It must be stressed that management of anticoagulation is a highly individualized process that is affected by ECMO flow rate, existing thrombus in the circuit, individual risk of bleeding, and numerous other clinical concerns. Anticoagulation is stopped at the time of decannulation.

COMPLICATIONS ON ECMO

Mechanical complications

Interruption or impairment of blood flow through the ECMO circuit is perhaps the most frequent and one of the most urgent issues faced by the ECMO practitioner. Elevated negative venous pressures may alert the clinician to intravascular volume depletion, cannula malposition, or kinks in the cannula or circuit tubing. In addition, pneumothorax, cardiac tamponade, and abdominal compartment syndrome should be considered if there is no readily appreciated mechanical reason for poor venous return. Intravascular volume depletion may be treated with infusions of crystalloid or colloid, as clinically indicated. In some conditions such as sepsis, there may be capillary leakage, in which case administration of significant fluid and resulting anasarca may be unavoidable. Management of oxygenator failure has been discussed previously. Accidental cannula dislodgement and tubing rupture are catastrophic and sometimes fatal events.

Neurologic complications

ICH is the most devastating complication of ECMO. Cranial ultrasound should be performed daily and after any major event, such as equipment malfunction, sudden worsening in oxygenation status, change in heparin requirement, or unexplained drop in hematocrit. EEG, as noted previously, is also helpful in the neurologic evaluation of the neonate. Other serious, if less acute, complications observed in the ECMO patient include long-term neurologic impairment (e.g., learning disorders, motor dysfunction, cerebral palsy) and may be due to hypoxia and acidosis prior to ECMO. During the ECMO course, frequent neurological examinations are performed, and neuromuscular blocking agents are avoided. Physical exam consists of evaluation of alertness and interaction, fullness of the fontanels, reflexes, tone, spontaneous movements, pupillary response and eye movements, and presence of seizure activity.

Renal complications

Infants on ECMO may sustain acute kidney injury (AKI) marked by oliguria and increasing BUN and creatinine levels. A single-center study from the Netherlands published in 2013 reported that two-thirds of neonates who required ECMO sustained AKI.[24] The authors observed significantly lower survival in those babies whose RIFLE score was "F" (failure of kidney function) and concluded that, since AKI in childhood may predispose to chronic kidney disease in adulthood, all infants who develop AKI while on ECMO should receive long-term monitoring of kidney function. The mechanism of AKI is likely multifactorial and includes both inadequate organ perfusion associated with the need for ECMO and effects of the circuit. The authors of the Netherlands study observed that the severity of AKI was greatest in the first 2 days of ECMO support. Both hemofiltration and hemodialysis have been used in conjunction with ECMO support and may help manage fluid volume status and electrolyte abnormalities.

WEANING FROM ECMO

As a patient recovers native cardiopulmonary function, ECMO support is gradually withdrawn. With VA support, which essentially involves the oxygenation and shunting of blood from the right atrium to the aorta, pump flow is gradually decreased. This results in increased pulmonary blood flow and transfer of the "work" of gas exchange and blood flow back to the patient from the circuit. Arterial and mixed venous blood gas analysis, in addition to standard hemodynamic monitoring, is used to assess patient readiness for decannulation. From starting flows as high as 150 cc/kg/minute, the flow is decreased to 30–50 cc/kg/minute while maintaining adequate perfusion. The ACT should be maintained at a higher level during periods of slow flow to prevent thrombosis. For cardiac patients, inotropic support is frequently reinstituted as mechanical support is withdrawn. Ventilator support is also increased above the "rest" settings used during ECMO support. Prior to complete withdrawal of ECMO, the cannulas are clamped and flushed with heparin–saline, and the blood is recirculated for a period of several hours through a shunt built in the circuit. This is done to confirm patient readiness prior to cannula removal. An alternative strategy that is appropriate for neonates supported with VV ECMO is to wean by reducing the oxygen content and flow of the sweep gas, and the relative equivalent of a clamp trial is accomplished by shutting off the sweep gas while maintaining flow through the circuit.

If the recirculation is tolerated, then decannulation is performed. As with the insertion, decannulation should be performed as a sterile surgical procedure. The patient should be placed in the Trendelenburg position, and muscle relaxants should be administered to prevent air aspiration into the vein. Prior to decannulation, alternative vascular access must be secured through which vasoactive medication and hyperalimentation are administered. Once the cannula is removed, the vein is ligated and not repaired. This is also usually true for the artery in the case of VA ECMO. Percutaneously placed dual lumen VV cannulas can be withdrawn and pressure applied for adequate time to achieve hemostasis.

ECMO IN INFANTS WITH CDH

Overall survival of infants with CDH has improved significantly with the use of permissive hypercapnia, spontaneous respiration, delayed surgery, and avoidance of ventilator-induced lung injury, and now exceeds 80% in many centers.[25–32] Among the most severely affected babies, however, active investigation into the best treatment methods continues. Prenatal markers of severity have guided the selection of patients to undergo fetal interventions, such as temporary tracheal occlusion, which provokes distension and growth of the lung ipsilateral to the diaphragmatic defect. Attempts to identify optimal postnatal treatments to further improve survival are active and ongoing, as many questions remain: What is the optimal timing of surgery for the most severely affected CDH patients? When is ECMO appropriate, and when is it futile? Is repair best accomplished on ECMO, or should ECMO be discontinued prior to repair? Which is the preferred mode of ECMO support in CDH patients, VA or VV? Data needed to provide conclusive answers to these questions are lacking, though literature exists to support many treatment options.

While it is widely recognized that CDH patients who require ECMO have a far lower survival rate than those who do not (51% and 95%, respectively),[1,25] this reflects differential disease severity between these two groups and is likely not an *effect* of ECMO. A study by the Congenital Diaphragmatic Hernia study group concluded that ECMO support did convey a survival advantage among the group of patients with the greatest predicted mortality.[33] The literature on this subject is almost exclusively retrospective in nature, and it is therefore difficult to establish a causal relationship between any individual therapy or treatment plan and improved survival. What seems clear is that ECMO can effectively rescue CDH patients from the cycle of pulmonary vasospasm, pulmonary hypertension, right-to-left shunting of blood, and worsening hypoxemia, hypercarbia, and acidosis that can ensue in the initial days of life. VV support offers the benefits of delivering oxygenated blood to the pulmonary vascular bed (and hence reverse pulmonary hypertension) and preserving the carotid artery. It also seems likely that the volume–outcome relationships that are demonstrated in many areas of medical care hold true for ECMO and CDH: high-volume centers are likely to have better outcomes.[25]

OUTCOME AND FOLLOW-UP OF NEONATES TREATED WITH ECMO

Mortality

In 1987, 653 neonatal respiratory ECMO runs were reported to the ELSO registry, and survival was 85%. In 2015, 627 runs were reported, and survival was only 63%. These numbers reflect a steady decline in reported survival of respiratory ECMO since the registry's inception.[1] The average run length has nearly doubled over the same time period (from 121 to 203 hours), while the longest reported run each year has quadrupled (411 to 1662 hours). Annual case volume peaked in 1992 at 1516 cases, and the fewest number of cases reported in a single year was 627 in 2015. These trends—longer runs, fewer cases, and increasing mortality—may all be the result of improvements in the medical management of critically ill newborns, and thus a sicker population of ECMO patients. Chronic respiratory failure from pulmonary hypertension has been a major cause for hospital readmission and late deaths, but mortality has remained specific to the primary diagnosis prior to ECMO.[1] This is understandable, since ECMO is more of a supportive, temporary organ replacement therapy than it is a treatment for any specific disease. ECMO patients with the diagnosis of CDH have about a 50% mortality rate, while the diagnosis of MAS carries only a 5% mortality rate.[1,30] The overall survival rate for respiratory ECMO patients reported to the ELSO registry since 1986 is 74%.[1]

The data for neonatal cardiac ECMO are somewhat different, as annual case volume has been generally increasing over the past 25 years, while survival has remained at 40%–45% without a clear trend over that time period. Of the infants who die on ECMO, about half die from severe bleeding complications. Another risk factor for mortality is a birth weight less than 2 kg. A retrospective study reviewed 300 newborns supported with ECMO, and the infants who weighed less than 2.5 kg, although meeting the criteria of 2 kg, had a relative mortality risk of 3.45% compared to ECMO neonates whose birth weight exceeded 2.5 kg.[34]

Feeding and growth sequelae

Following successful decannulation from ECMO, an important determinant of readiness for discharge from the neonatal intensive care unit (NICU) is successful enteral feeding. Feeding problems have been reported in as many as one third of ECMO-treated infants and vary in presentation.[32–34] Feeding difficulties are less often a complication of ECMO and more often related to the infant's underlying disease.

Problems with feeding that present soon after completion of the ECMO course include interference from tachypnea, generalized CNS depression, poor hunger drive, pain related to endotracheal intubation, poor oral–motor coordination in an infant who has never been nipple fed, and vagal neuropraxia from manipulation or compression of the vagus nerve during the cannulation procedure.[37,38] While this last effect, specifically recurrent laryngeal nerve injury, is a well-described complication of surgery on the aortic arch and ligation of the patent ductus arteriosus, it is not observed to a significant degree among infants who have undergone ECMO cannulation. ECMO support in and of itself generally does not cause major long-term feeding problems. The feeding problems that are observed after an ECMO course are more related, rather, to the pre-ECMO diagnosis. For example, infants with CDH have a higher incidence of feeding difficulty than infants with MAS and respiratory distress syndrome (RDS).[35–37] CDH patients have associated foregut

dysmotility that leads to significant reflux, delayed gastric emptying, and feeding difficulties. Respiratory compromise and severe chronic lung disease also interfere with sucking and swallowing. These babies may require prolonged nasogastric feeding or even a gastrostomy, fundoplication, and pyloroplasty to maintain adequate growth.

Although normal somatic growth is most commonly reported, ECMO-supported children are more likely to experience problems with growth than normal controls. Head circumference below the fifth percentile occurs at a higher rate (10%) in post-ECMO children. Furthermore, poor head growth is associated with a major handicapping condition with a risk greater than 75% at 5 years of age.[38] Growth problems are most commonly associated with those ECMO patients who are afflicted by CDH or residual chronic lung disease.[39]

Respiratory sequelae

Significant respiratory problems are reported in ECMO survivors during the first 2 years of life, with a high rate of rehospitalizations for pulmonary conditions.[40,41]

Approximately 15% of infants supported with ECMO require oxygen at 28 days. By the age of 5 years, ECMO patients were twice as likely to have a reported case of pneumonia as control children (25% versus 13%). Approximately half of the ECMO children with pneumonia were hospitalized compared to none of the control cases. Half of the cases of pneumonia in ECMO children occurred before 1 year of life compared to none in the control group. In addition, more than half of the ECMO rehospitalizations for pneumonia occurred within the first 6 months of life.

Among ECMO-treated neonates, the primary diagnosis of CDH, in particular, has been found to be associated with chronic lung disease as defined by the need for bronchodilators, diuretics, or supplemental oxygen for the management of pulmonary symptoms. Specifically, the use of supplemental oxygen at discharge from the hospital has been reported in 22%–80% of CDH patients.[39,42–44] Ventilator management that employs high airway pressures and oxygen concentration, as well as preexisting lung injury prior to initiating ECMO, leads to the development of BPD in these children. Persistent oxygen requirements may be due to pulmonary hypertension.

The age at the time of ECMO, which frequently correlates with the duration of mechanical ventilation prior to ECMO, is another factor associated with need for supplemental oxygen beyond 28 days of life.[8] Neonates with severe respiratory failure had an 11.5-fold increased risk of BPD if ECMO was initiated later than 96 hours of age. In addition, ECMO-treated infants with birth weights of 2–2.5 kg have a greater risk for chronic lung disease than do larger infants.[34]

Neurodevelopmental sequelae

Perhaps the most serious of post-ECMO morbidities is sensorineural handicap. Robust data on long-term neurologic outcome for newborns treated with ECMO are lacking. Reports of neurodevelopmental outcome after 1 year of age have been published from multiple institutions. Among 540 ECMO survivors from 12 institutions, the total rate of sensorineural handicap (cerebral palsy, blindness, hearing impairment) is 6% on average, ranging from 2% to 18%.[38,45–57] Significant developmental delay among ECMO survivors is 9% on average, ranging from 0% to 21%. This is comparable to other critically ill neonates. For example, newborns with extremely low birth weight (<750 g) have a 15% rate of major sensorineural handicap, with 21% testing in the mentally retarded range.[58] Additionally, newborns with PPHN not supported with ECMO have an average sensorineural handicap rate of 23% (0%–37% range) among 162 survivors from eight institutions.[59–66]

At 5 years of age, 50% of children supported with ECMO as neonates had a normal neurologic outcome as defined by lack of a developmental delay, epilepsy, or cerebral palsy.[67] The remaining children had varying degrees of disability, mostly of low severity. These authors also found that low gestational age and low birth weight were significantly associated with a negative neurologic outcome. This further supports the notion that preexisting factors, as well as ECMO support itself, contribute to negative neurologic outcomes.

The underlying diagnosis requiring ECMO support is related to risk of subsequent cognitive impairment. At an average age of 31 months at follow-up, children with CDH supported by ECMO were more likely to have an abnormal cognitive status than non-CDH ECMO survivors. Male gender and limited maternal education were other risk factors for abnormal cognitive development.[55]

Auditory deficits are reported in more than 25% of ECMO-supported neonates at the time of discharge.[68] The majority of these are mild–moderate in severity, as measured by brainstem auditory evoked response testing, and some may resolve over time. These auditory deficits may also be caused by furosemide or gentamicin ototoxicity. As a result, hearing screening is recommended at the time of NICU discharge. Examining data for 313 ECMO children from five centers shows an overall rate of 9% (range 4%–21%).[38,50,52,54] This rate is not higher than that reported for infants with PPHN who were not treated with ECMO (23%, range 0%–37%).[59–62]

Visual deficits observed among ECMO-treated neonates are usually due to the underlying retinal immaturity of premature patients. Visual deficits are rarely seen in ECMO-treated neonates weighing more than 2 kg. Concern for retinopathy of prematurity due to the hyperoxic condition of ECMO has proven to be unfounded. Haney et al.[69] reported ocular findings in 16 of 85 neonatal ECMO patients. These findings included vascular immaturity, vitreous and retinal hemorrhage, and optic nerve atrophy.[69] Not all infants were examined in this study, however, and there may have been additional complications. Long-term sequelae were not reported, and non-ECMO controls were not tested. In a study of 86 newborns supported with ECMO at the Children's Hospital of Los Angeles, examined (on average)

3 weeks after decannulation, Gonzalez et al.[70] found that 73 (85%) had normal exams, and they concluded that routine ophthalmologic screening after ECMO may not be needed.

Seizures, both clinical and electroencephalographic, are widely reported among ECMO-treated neonates, with an incidence ranging from 20% to 70%.[71–74] However, the timing and type of seizure activity vary. In a group of 5-year-old ECMO survivors, only 2% had a diagnosis of epilepsy. Seizures in the neonate are associated with neurologic disease and poorer long-term outcome, including cerebral palsy and epilepsy.[75] According to one study, the handicap rate following neonatal seizures is 8%.[76] A predictive association between abnormal EEG and developmental status has been found: 18% of infants having normal EEGs go on to have developmental delays, while delays are observed in 35% of infants with one abnormal EEG and 58% of ECMO-treated infants with two or more abnormal EEGs.[72]

Neuromotor deficits observed in ECMO survivors range from mild hypotonia, gross motor delay, and asymmetry to isolated cases of spastic quadriparesis. Although moderate hypotonia is not uncommon at discharge, it generally improves over the next 4–6 months. It should be noted that these neuromotor findings are also seen in normal control children.[41] The incidence of severe non-ambulatory cerebral palsy is less than 5%.[38,45,50] These cases are generally accompanied by cognitive disability, demonstrating a global insult to the brain. Mild cerebral palsy is seen in up to 20% of children supported with ECMO in the newborn period.

Survivors of neonatal ECMO, as a group, most commonly function within the normal range.[38,45,47,50–57,77] The rate of major handicap appears to be stable across studies with an average of 11% (range 2%–18%).

By hospital discharge, at approximately 1 month of life, ECMO-treated infants still exhibit signs of general CNS depression including lethargy, hypotonia, and weak primitive reflexes, these being indicators of moderate hypoxic–ischemic insult. By 4 months of age, ECMO-treated infants typically function within the normal range defined by Bayley mental and motor scales. Residual hypotonia or mild asymmetry persists in about 25% of ECMO patients. Mild motor delay usually accompanies the hypotonia. Significant neurological abnormalities and motor deficits (more than two standard deviations below norm) are found in approximately 10%–15% of ECMO survivors. By 3 years of age, the rate of handicap appears to be stable, but more subtle abnormalities manifest at this age, such as learning disability, particularly with language and perceptual functioning.[78–80] By age 5, a diagnosis of mental retardation (IQ < 70, delay in social adaptive functioning) becomes more certain. In one 5-year group, 11% of individuals studied were diagnosed as mentally retarded, most in the mild range with IQs of 50–70.

For ECMO children who had carotid artery cannulation and ligation, controversy remains over reconstruction of the artery. Baumgart et al. reported experience of 84 ECMO children who had carotid ligation and 41 who had right common carotid artery reconstruction.[81,82] Failure of the reanastomosis, defined by >50% occlusion or no flow, occurred in 25% of procedures. No significant differences were reported for occurrence of grades 3 and 4 hemorrhages, but more patients in the carotid repair group had moderate to severe abnormalities on EEG (60% of the reanastomosed group, compared to 35% of the nonreconstructed group). Despite this, no differences were reported in the proportion of significant neurodevelopmental delays. An additional report of neonates with CDH supported by ECMO showed a 72% incidence of occlusion or high-grade stenosis of the repaired right common carotid artery as measured by MRI at 2 years of age.[83] A more recent study reports a higher patency rate of 84% when measured by ultrasound at a median interval of 63 days following decannulation.[84] Neither study demonstrated a significant difference in neuroimaging results or neurologic outcome associated with carotid repair versus ligation.

SUMMARY

Since the first use of ECMO in neonates in 1974, much has been learned about the treatment of infants with cardiac and respiratory disease. New medications and advances in mechanical ventilatory support have been developed, which may have helped numerous babies survive and avoid ECMO cannulation, and in fact the use of ECMO for respiratory indications has been declining, from a high of 1,516 cases in 1992 to only 627 cases in 2015 (there has been an opposite trend for neonatal cardiac ECMO).[1] Qureshi et al.[85] note other interesting trends, specifically that CDH has supplanted MAS as the commonest indication for neonatal respiratory ECMO. This shift has accompanied a decreasing survival from respiratory ECMO; in 2015, survival fell to a historic low of 63%. Improved treatment for meconium aspiration has resulted in a proportional decrease in cannulations among the group with the best survival, and hence reduced overall survival. Survival to hospital discharge of infants with CDH who require ECMO support remains poor at 51%.[1]

Technological advances and improvements in ECMO circuit components continue to be made, and indications for ECMO support continue to be expanded and refined. Whereas historically many centers would not offer ECMO to infants for whom CPR was in progress, this is no longer the case. In fact, cannulation in the setting of cardiac arrest refractory to CPR (termed ECPR) is being performed with increasing frequency. In 2015, 1,254 cases of ECPR were reported to the ELSO registry, with rates of survival to decannulation and to hospital discharge of 64% and 41%, respectively. Notably, these results do not differ substantially from survival data for ECMO done for cardiac indications (not in the setting of cardiac arrest). ECMO continues to play a role in the treatment of a variety of neonatal respiratory diseases in addition to meconium aspiration and CDH. Among these diseases are persistent pulmonary hypertension of the newborn, sepsis, and pneumonia.

Challenges remain in achieving improved survival in diseases like CDH and sepsis, where survival remains poor despite the use of ECMO as a bridge to recovery. Challenges also exist in refinement of inclusion and exclusion criteria that maximize survival rates but avoid ECMO in infants with irreversible disease, high risk of ECMO-related morbidity, or very low likelihood of survival. Exclusion criteria include early gestational age, low birth weight, coagulopathy, ICH, lethal congenital anomalies, severe brain injury, and irreversible lung disease.

In summary, indications for ECMO support have evolved over the past decade, with increased use of ECMO in the setting of cardiac arrest refractory to CPR, a decrease in use for respiratory indications, and an increase in use for cardiac support. ECMO has moved into more widespread use, as indicated by the steady increase in ECMO centers over the past 10 years. It remains an important therapeutic and life-sustaining tool in the treatment of any hypoxic or hypotensive infant who has a reversible pulmonary or cardiac condition, who is physically large enough for cannulation, and who has failed maximal medical therapy. Meticulous attention and thorough documentation of each ECMO patient through the international ELSO registry will lead to continued improvement in safety, efficacy, and appropriateness of this important technology.

Bronchoscopy in the newborn

MIRA SADADCHARAM, ROHIT UMESH VERMA, AND JOHN D. RUSSELL

INTRODUCTION

The infant larynx presents some different aspects compared to the adult. Its location is higher in the neck, the cricoid cartilage being located approximately at the fourth cervical vertebra. With the growth of the child, the cricoid cartilage will gradually descend to the level of the seventh cervical vertebra, which is the location in adulthood. The size of the larynx in the newborn is about 1/3 of that in the adult. Their structures such as the vocal process of arytenoid, cuneiform cartilage, the arytenoids, and the soft tissue that makes up the supraglottic larynx are also bigger. The epiglottis is proportionally more posterior and narrower and more tubular or omega-shaped (Figure 45.1).

Bronchoscopy in the newborn is an important diagnostic and therapeutic tool.[1] The small size of the pediatric airway, anatomic differences in the pediatric larynx, as well as the distinct subset of pathologies unique to the pediatric population are all factors to be cognizant of when performing endoscopic examination in a child. Diagnosis of congenital laryngotracheal malformations and management of airway complications secondary to prolonged intubation are the two commonest indications for pediatric bronchoscopy.[2] The first pediatric bronchoscopy was performed by Killian in 1895.[3] At that time, the procedure was associated with a high complication rate due to poor visibility through small-diameter bronchoscopes, lack of a satisfactory light source, and difficulty maintaining ventilation during the procedure. Modern Hopkins lens systems, intense yet "cold" light sources, together with modern anesthetic techniques have facilitated safer examination of the airway in the newborn.[4,5] Pediatric flexible bronchoscopy was initiated in the mid-1970s, after Ikeda introduced the flexible bronchofiberscope in 1968. Since then, newer and smaller instruments and the addition of suction channels have enabled the endoscopist to examine the airway without significantly distorting the anatomy or normal physiology. Currently, flexible bronchoscopy has largely superseded rigid bronchoscopy for diagnostic purposes in the lower airway.[6,7] The development of the pediatric fiber-optic nasendoscope, while not permitting a view of the trachea or bronchi, has dramatically changed airway endoscopy in the newborn. Infants with stridor who are otherwise well can have their larynx and upper airway examined at the bedside or the outpatient clinic. If a diagnosis of laryngomalacia is made and no suspicious features are noted in the clinical history, laryngoscopy and bronchoscopy under general anesthesia may not be required. However, the airway control and therapeutic ability of rigid bronchoscopy have not been replaced, and it remains an important and potentially lifesaving procedure.

ANESTHESIA FOR PEDIATRIC BRONCHOSCOPY

Anesthesia for diagnostic/therapeutic procedures on the airway has always been challenging. Success is dependent upon careful planning and constant communication between the endoscopist and anesthetist throughout the procedure. Preoperative evaluation consists of a detailed clinical history and physical examination. As a general rule, children are recommended to fast for 6 hours if fed on formula, 4 hours if breast-fed, and 2 hours after the ingestion of clear fluids. Anesthetic technique is dependent upon the child's physical status, the presence of chemical/physical trauma to the airway, and the presence/absence of coexisting lower respiratory tract infections with consequent increased risk of bronchospasm, secretions, edema, hypoxia, and acidosis. In addition, the needs of the endoscopist in performing diagnostic/therapeutic interventions, e.g., bronchoalveolar lavage (BAL), and foreign body retrieval will need to be taken into consideration to ensure the safety of the child and minimize the risk of complications. In many instances, the perioperative use of bronchodilators and/or anticholinergic drugs may improve oxygen saturations and alveolar ventilation while attenuating the vagal responses of bradycardia and bronchoconstriction during airway manipulation.

Figure 45.1 Tubular or omega-shaped epiglottis of children. The normal glottis of the infant has a very small opening, about 7 mm in anteroposterior dimension and 4 mm in the posterior transverse dimension. Following Poisseuille's law, we know that resistance to airflow is inversely proportional to the fourth power of the radius. As such, halving the radius increases resistance 16 fold.

With the exception of remifentanil, which is rapidly metabolized in neonates, as a general rule, the smaller the child, the more incomplete their metabolism, specifically in relation to drugs. The reduced intracellular calcium stores and lower myocardial mass in neonates and small children render this population susceptible to the cardiodepressant effects of anesthesia. Moreover, neonates in general and preterm neonates in particular are prone to postanesthesia apnea.

RIGID BRONCHOSCOPY

Indications for rigid bronchoscopy

Rigid bronchoscopy can be performed for both diagnostic and therapeutic purposes (Table 45.1). The commonest causes of stridor and airway obstruction in a neonate are laryngomalacia, subglottic stenosis (both congenital and acquired), and vocal cord paralysis.[8,9] Less common causes include laryngeal clefts, hemangiomas, and papillomas. Rigid bronchoscopy is the diagnostic procedure of choice in the management of airway obstruction. Most neonates with stridor will have laryngomalacia and can be diagnosed with fiber-optic laryngoscopy in an outpatient setting. However, there are three clinical situations where neonates with stridor warrant rigid bronchoscopy: (1) the neonate with severe stridor and significant airway obstruction, who will require urgent bronchoscopy and airway support; (2) the neonate with initially stable but deteriorating stridor; and (3) the neonate with mild or moderate stridor but with poor weight gain or difficulty in feeding, apnea, or cyanotic episodes. Adjuvant investigations may suggest a particular diagnosis, e.g., a vascular ring on barium swallow. However, endoscopy is needed to confirm this diagnosis. In neonates with recurrent aspiration, rigid bronchoscopy is necessary to rule out a laryngotracheal cleft. Even if pathology is found in the larynx, it is important to complete a systematic assessment as about 70% neonates undergoing rigid bronchoscopy have more than one airway pathology.[4]

Table 45.1 Indications for rigid bronchoscopy

Persistent unexplained cough or wheeze
Unexplained dyspnea or stridor
Suspected congenital airway anomalies, e.g., subglottic stenosis
Foreign body removal
Hemoptysis
Recurrent lower respiratory chest infections
Persistent abnormalities on chest radiograph
Diagnostic BAL
Lung abscess
Thoracic trauma
To remove benign tumors (recurrent respiratory papillomatosis)
Endoscopic management of strictures, webs, granulation tissue
Open airway surgery

Instrumentation

A systematic assessment of the neonatal airway should be performed, which incorporates laryngoscopy, tracheoscopy, and bronchoscopy. A wide range of equipment of varying sizes is required including laryngoscopes, bronchoscopes, telescopes, and telescopic forceps. The senior author's preference is for Karl Storz telescopes and the Benjamin–Lindholm laryngoscope. Suspension of the laryngoscope on a Mayo stand is essential for therapeutic procedures and freeing the surgeon's second hand (Figure 45.1). The components of a modern bronchoscope are (Figure 45.2)

1. A closed gas system allowing connection to an anesthetic circuit
2. A rigid Hopkins rod telescope to allow distal illumination and vision
3. A side channel for the passage of suction catheters or flexible forceps

The bronchoscopes range in size from 2.5 (outside diameter 4.0 mm) to 6.0 (outside diameter 8.2 mm). Sizes 2.5–3.0 are the most appropriate for neonates (Table 45.2).

Technique of rigid laryngobronchoscopy

Rigid laryngobronchoscopy requires general anesthesia. Modern techniques are versatile and controlled, allowing an unhurried and complete examination.[8,9] A full range of neonatal and pediatric laryngoscopes, bronchoscopes, and telescopes are essential. Modern 1 chip and 3 chip cameras allow magnification and excellent resolution of the image on screen of these tiny airways.

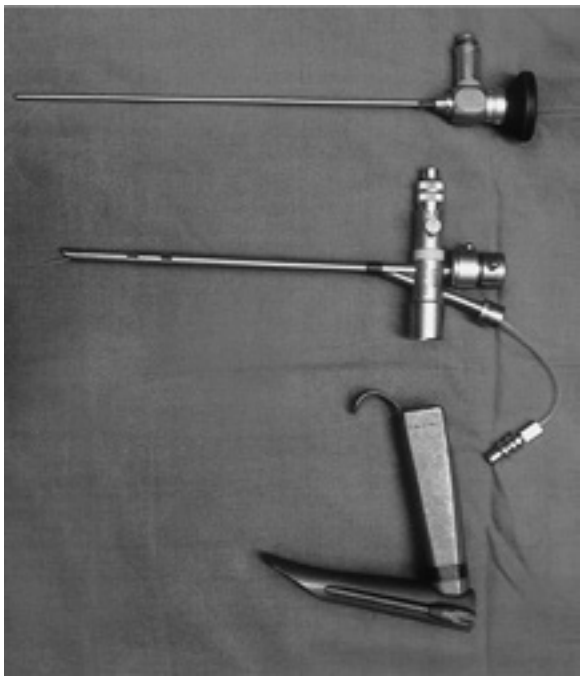

Figure 45.2 Equipment for rigid laryngobronchoscopy: 0° telescope (top); 2.5 mm ventilating bronchoscope (middle); Benjamin–Lindholm laryngoscope (bottom).

Table 45.2 Size of rigid bronchoscopes according to age

Patient age (mean)	Size	Outside diameter (mm)
Premature infant	2.5	3.7
Term newborn (birth to 3 months)	3	4.8
6 months (3–18 months)	3.5	5.7
18 months (1–3 years)	3.7	6.3
3 years (1.5–5 years)	4	6.7
5 years (3–10 years)	5	7.8
10 years (>10 years to adolescent)	6	8.2

A spontaneous respiration technique is the anesthetic method of choice and has superseded transglottic jet ventilation. However, this technique is challenging to the anesthesiologist requiring a balance as the patient must spontaneously breathe, while sedate enough to not develop laryngospasm or bronchospasm when instrumentation is introduced. Sevoflurane is, in most anesthesiologists' opinion, the anesthetic of choice. It allows a deep plane of anesthesia without causing respiratory arrest. The procedure should proceed in a systematic manner as outlined next.[10]

The neonate is anesthetized with a mixture of sevoflurane and oxygen via a facemask. The patient's chest is not covered with drapes so that respiration can be assessed. The surgeon sits at the head of the bed with the anesthetic machine positioned to the side in such a way that both the surgeon and the anesthesiologist should be able to read the patient's vital

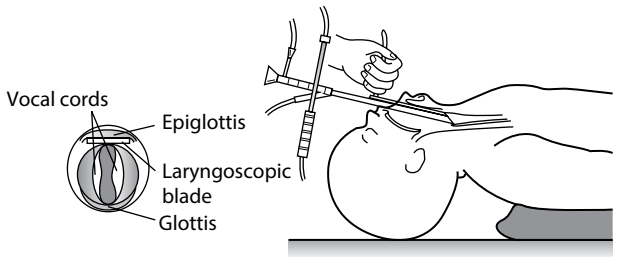

Figure 45.3 Under direct visualization of the larynx, the bronchoscope is introduced into the trachea.

signs including oxygen saturation. The camera system's monitor should be positioned over the far end of the bed. The larynx is then briefly visualized using the laryngoscope and topical 4% lidocaine (0.5–2 mg/kg) applied (to prevent laryngospasm). An appropriately sized nasopharyngeal airway is inserted, and the anesthetic agent is then provided via this route. Atropine may also be administered to prevent bradycardia and to dry up the secretions during the assessment. A baby Lindholm laryngoscope is then inserted, by placing its tip in the vallecula, exposing the whole larynx. The scope is suspended on a Mayo table to avoid compression of the baby's chest or held with the nondominant hand. The larynx is now examined using a 4 mm 0° Hopkins rod laryngeal telescope. Pathological conditions looked for in the larynx include (1) laryngeal webs, (2) laryngeal cysts, (3) subglottic stenosis, and (4) hemangiomas. The mobility of the arytenoids is then assessed using a blunt laryngeal probe, which also allows palpation for small laryngeal clefts. Once the larynx has been thoroughly examined, the telescope is passed into the subglottis and trachea. This allows a complete atraumatic inspection, easily passing to the carina. In order to examine the bronchi in detail, one has to remove the laryngoscope and introduce an appropriately sized bronchoscope (Figure 45.3). Turning the baby's head to the left allows entry through the right main bronchus, and turning the head to the right allows entry into the left mainstem bronchus. On both the left and right sides, access to the upper lobe bronchus is the most challenging and may be aided by various dynamic maneuvers including flexing the infant's chin onto the shoulder and external pressure on the chest. The final part of the assessment is to examine the trachea and vocal cords as the baby is lightening up from the anesthetic. This is the only time when tracheobronchomalacia and vocal cord paralysis can be observed.

Advantages of rigid bronchoscopy

The major advantage of rigid airway assessment is the excellent control of ventilation provided. This is of particular importance with the soft and collapsible neonatal airway. The rigid bronchoscope can also accommodate instruments, allowing therapeutic interventions to be performed endoscopically. Rigid bronchoscopy allows the lower airways to be inspected safely and in great detail while maintaining control over ventilation. Flexible bronchoscopy does

not allow such control and in a small neonate or infant will cause significant, if not total, airway obstruction. The image quality obtained by the rigid telescope is also superior to that obtained with the flexible fiber-optic bundles.

Complications of rigid bronchoscopy

Despite the relative safety of modern rigid bronchoscopy, complications still occur with a reported complication rate of 2%–4%. Safety is affected by the anesthetic technique (including intraoperative monitoring), the interventions performed during the endoscopy, availability of equipment, the expertise of the staff, and the condition of the patient.[5] Complications reported include laryngospasm, vocal cord trauma, subglottic edema, pneumothorax, pneumonia, hoarseness, hemorrhage, cardiac arrhythmia, and death. In Hoeve et al.'s series in 1993, a diagnosis of tetralogy of Fallot, undertaking biopsy or drainage, foreign body extraction, and tracheal stenosis were the main risk factors for complications. Interestingly, fewer complications occurred in the age group <3 months.[11]

FLEXIBLE BRONCHOSCOPY

Flexible bronchoscopy was first performed in the 1970s, and since then, newer and smaller scopes have enabled visualization of the airway of premature infants and neonates.[12] The advantages of flexible airway bronchoscopy are that examination of the distal lobar bronchi is less challenging than rigid bronchoscopy, it can be performed as a day-case procedure, and it requires little preparation except for no oral intake 4–6 hours preoperatively. Provided flexible bronchoscopy is performed by an experienced operator in a controlled setting, the procedure is very safe. Vauthy[6] reports over 10,000 flexible bronchoscopies with no mortality.

Indications for flexible bronchoscopy

Flexible bronchoscopy may be performed for diagnostic reasons in the neonate with mild stridor, unexplained wheezing, hemoptysis, chronic cough, persistent atelectasis, and persistent pulmonary infiltrates (Table 45.3).

Table 45.3 Indications for flexible bronchoscopy

Diagnostic	Therapeutic
Unexplained stridor	To aid intubation
Unexplained wheezing	Therapeutic BAL
Hemoptysis	Brush biopsies
Unexplained cough	Removal of airway secretions
Persistent atelectasis	Diagnose and monitor after lung transplantation
Recurrent or persistent pulmonary infiltrates	Transbronchial biopsy

Flexible bronchoscopy is also increasingly performed in the neonatal intensive care unit (NICU).[13–15] Flexible bronchoscopy in the NICU can be performed via the existing endotracheal tube or tracheostomy (thus maintaining the airway) and negates the need to transfer the patient to the operating room. The bronchoscope can be used to check the position of the endotracheal tube. Sudden respiratory deterioration in the ICU can be due to severe mucous plugging, atelectasis, granuloma formation, tracheitis, or tracheobronchomalacia. In these patients, flexible bronchoscopy may be both diagnostic and therapeutic, allowing careful direction of suction catheters to improve pulmonary toilet. Full-term infants tolerate flexible bronchoscopy with a 3.4 mm scope, which has suction channels for insufflation of oxygen, suction and bronchial brushings, or BAL. BAL aids the diagnosis of infection, gastroesophageal reflux (detecting lipid-laden alveolar macrophages), and the removal of mucous plugs.[16,17]

Technique of flexible bronchoscopy

Pediatric flexible bronchoscopy can be performed directly through the nose or mouth, via a face mask or laryngeal mask airway, as well as through an endotracheal tube.[15] It is the author's experience that the vast majority of patients require general anesthesia for flexible bronchoscopy. The neonate is placed on the table with the assistant providing oxygen via a mask. The average diagnostic procedure lasts approximately 30 seconds and should be digitally recorded, so that the procedure can be reviewed. If performed as a day-case postprocedure, the patient should be clinically observed for 1.5 hours and allowed to eat prior to discharge.

Common pitfalls for the unwary flexible bronchoscopist

CONCURRENT LESIONS

Children frequently have multiple airway abnormalities, and these can often be missed due to the speed of the flexible assessment.

DIFFICULT NASAL PASSAGE

Nasal septal deviations or turbinate hypertrophy can lead to difficulty passing the flexible scopes. The use of a topical vasoconstrictor enables the nose to be entered in most cases. Wood et al. in 1990 encountered only three patients in whom the transnasal passage of the flexible bronchoscope was not possible.[20]

PHARYNGEAL HYPOTONIA

Patients with tracheostomies or who have reduced muscle tone because of neurologic disease often have pharyngeal hypotonia leading to an increase in the amount of secretions in the larynx, making visualization difficult.

Complications of flexible bronchoscopy

Complications of flexible bronchoscopy are generally minor and are reported to occur in 2%–8% of the cases.[18–21] Reported complications include laryngospasm, pneumothorax, epistaxis, bradycardia, and hemorrhage. Generally, high-risk patients are more likely to undergo rigid bronchoscopy as obstruction of a large proportion of the airway can lead to hypoxemia. It is also difficult to remove foreign bodies with a flexible scope. The relative contraindications to flexible bronchoscopy are (1) hypoxemia, (2) respiratory distress, (3) hemorrhagic diathesis, (4) cardiac arrhythmia, and (5) a foreign body. All these problems increase the risk of complications with flexible bronchoscopy.

BAL in children

Since the advent of flexible bronchoscopy in the 1980s, bronchoscopy has been increasingly used as a diagnostic tool for several pediatric pathologies.[22,23] The technique of BAL has helped determine the diagnosis in a number of respiratory conditions including persistent/recurrent lower respiratory tract infections, interstitial pulmonary infiltrates, severe refractory lower respiratory tract infections in the setting of the ICU, and pulmonary infiltrates in immunocompromised children.[24–29] Within this context, BAL is a safe, fast procedure. It is particularly useful in children in whom it is often difficult to obtain a sputum sample. Microbiologic assessment of BAL fluid may aide in identifying a causative pathogen. Even if the BAL sample is small, molecular biology techniques frequently allow for amplification and identification.[30] In addition, diagnoses of alveolar proteinosis, hemosiderosis, and recurrent pulmonary aspiration (based on the presence of lipid-laden macrophages) can also be made on the basis of BAL, potentially obviating the need for open/transbronchial biopsy. Furthermore, BAL may be used in a therapeutic capacity, e.g., in the treatment of alveolar proteinosis and for removal of inspissated secretions in children with cystic fibrosis and foreign body removal.[31,32]

CONCLUSION

Modern rigid and flexible bronchoscopy in the newborn carried out by trained personnel is a safe, relatively atraumatic procedure with a low rate of serious complications. This is due to the advances in anesthesia, pharmacology, instrumentation, and camera technologies. Rigid and flexible bronchoscopy should be viewed as complimentary and not competing mutually exclusive techniques. Both procedures should be in the armamentarium of the pediatric airway surgeon. There are advantages and disadvantages to each technique. It is to the neonate's advantage to have both types of endoscopes available so the procedure with the highest benefit-to-risk ratio can be employed.

Esophageal atresia and tracheo-esophageal fistula

PAUL D. LOSTY

To anastomose the ends of an infant's esophagus, the surgeon must be as delicate and precise as a skilled watchmaker. No other operation offers a greater opportunity for pure technical artistry.

Willis Potts
1950[1]

INTRODUCTION

Surgery for esophageal atresia (EA) is widely regarded as one of the greatest milestones in newborn surgery. Significant advances have now led to greater than 95% survival for EA babies managed in the modern era with much attention now focusing on morbidity, health outcome(s), and quality of life (QoL) in adult survivors. Classical operation with muscle sparing thoracotomy, axillary skin crease incision, and minimally invasive surgery provide a selection of strategies for the pediatric surgeon and enthusiast. Controversy dominates best practice with regard expert management of pure (long-gap) EA without fistula, medical and surgical treatment of gastroesophageal reflux (GER) disease, therapies for anastomotic stricture, and tracheomalacia. Embryology and molecular genetic studies have yielded fascinating insight into the etiology of EA and tracheoesophageal fistula (TEF), with many important contributions emerging from animal models sharing striking similarity to the human phenotype.[2,3]

HISTORY

The history of EA–TEF is well described in the literature.[2,3] First survivors were not recorded until 1939 with Leven and Ladd achieving success with staged esophageal repair. Cameron Haight (an American surgeon working in Ann Arbor, Michigan) is credited with the first successful primary repair and survival of a 12-day-old female newborn. UK success then followed with Franklin (1947) at the Hammersmith Hospital, London; Denis Browne (1948) at the Great Ormond Street Hospital for Sick Children, London; and Peter Paul Rickham (1949) at Alder Hey Children's Hospital, Liverpool. By the 1980s, pediatric surgery units in the developed world were achieving outcomes approaching 85%–90% survival with mortality falling to less than 10%, defining the modern era of care.[2]

CLASSIFICATION

In 1929, Vogt[4] first proposed an anatomical classification of EA and TEF based on radiological and postmortem findings. A variety of surgical classifications were thereafter suggested as operative treatment became more successful, the most frequently deployed system being that attributed to Gross[5]. The most detailed classification, however, is credited to Kluth[6] and incorporates all described anatomical variants of EA and TEF. From a practical viewpoint, a working classification based on the frequency of each anomaly is of greatest value to the neonatal surgeon (Figure 46.1).

PROGNOSIS

Waterston et al.'s[7] landmark paper describing the influence of pulmonary disease, birth weight, and associated congenital

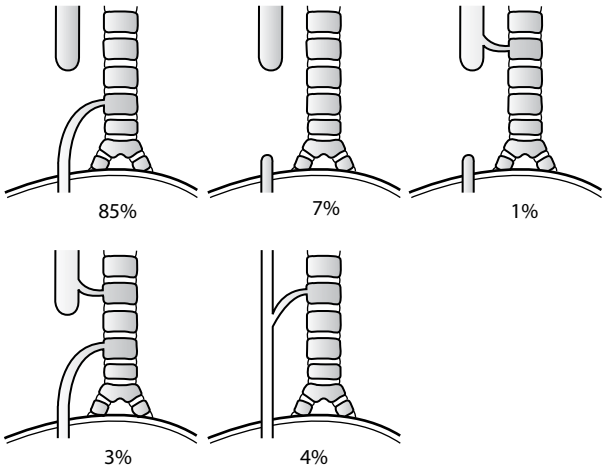

Figure 46.1 Classification and frequency of EA and TEF. EA and distal TEF—85%; isolated EA—7%; H-type TEF—4%; EA with proximal and distal fistulas—3%; EA and proximal fistula—1%.

Table 46.1 Spitz prognostic classification scoring system—survival related to birth weight and congenital heart disease (CHD)

Group		Survival
I	Birth weight ≥1500 g without major CHD	97%
II	Birth weight <1500 g or major CHD	59%
III	Birth weight <1500 g and major CHD	22%

anomalies on outcome of newborns with EA–TEF provided an important contribution for development of prognostic scoring systems. Advances in neonatal intensive care have now rendered the Waterston classification outdated. Spitz et al.[8] provided a new risk grading system based on birth weight and presence or absence of congenital heart disease that is now widely accepted as applicable to the modern era (Table 46.1). A Montreal classification system places greater emphasis on preoperative ventilator dependence and associated major anomalies as survival determinants.[9] Many studies record the negative influence of respiratory distress syndrome and pneumonia on outcome(s) and the burden of aspiration events contributing to morbidity and late death following operative repair.[10,11] Variant anatomy also features as risk factor(s) for determining favorable outcome(s). Babies with "long gap" or "pure" EA without fistula experience a high morbidity from anastomotic leak, stricture, fundoplication rate(s), "failure"/"redo" operations, and esophageal replacement.[10–12]

EPIDEMIOLOGY

In the Liverpool and Mersey region, the incidence of EA and TEF is 1 in 3300 live births.[13] The reported rates vary widely across the world from 1 in 2440 in Finland[14] to 1 in 4500 in Australia[15] and the United States.[16] Sex ratio has been quoted as equal by many authors, but some publications allude to a male preponderance.[17] EA and TEF are more common in twin pregnancies. Exposure to teratogenic drugs during pregnancy has been implicated; these include thalidomide, progesterone, and estrogens.[18]

GENETICS

Sporadic reports of familial cases of EA–TEF suggest a polygenic hereditary etiology. The best estimate of risk of recurrence for parents of a single affected child is 0.5%–2.0%, rising to 20% if another sibling is born with EA. The vertical transmission risk is 3%–4%.[19] A 10% incidence of nonspecific chromosomal abnormalities (translocations, deletions, and duplications) is recorded. Edwards syndrome (trisomy 18) and Down's (trisomy 21) are associated with the EA and TEF phenotype. Recognition of a syndrome suggestive of a major chromosomal abnormality in EA and TEF should prompt urgent involvement of a clinical geneticist before corrective surgery is undertaken. EA–TEF has also been described in association with Feingold syndrome (autosomal dominant), Holt–Oram syndrome, DiGeorge sequence, polysplenia, and in babies with Pierre Robin anomaly.[19]

ANIMAL MODELS

Significant contributions to understanding the embryology and genetic control of foregut development have evolved from laboratory research involving animal models of EA and TEF. The Adriamycin rodent model was developed by Diez-Pardo et al.[20] in Madrid. Timed pregnant rodents administered with Adriamycin (doxorubicin) in the prenatal period on gestational days 8 and 9 yield offspring with an EA–TEF variant phenotype.[20] Pups also have associated VACTERL spectrum anomalies—vertebral, anorectal, cardiac, tracheoesophageal, radial/renal, and limb defects.[21] A murine model of the VACTERL syndrome has also been generated in mice with targeted deletions of the transcription factors Gli-2 and Gli-3 for the Sonic hedgehog (Shh) gene—pivotally linked with axial organogenesis. Gli-2–/–Gli-3–/– double mutants demonstrate the full phenotypic spectrum of VACTERL syndrome, thus confirming a crucial role for Shh in genetic control of foregut development.[21,22]

EMBRYOLOGY

There is no unifying embryological theory that successfully explains all the anatomical variants of EA and TEF. The complete pathology has been demonstrated in the 5-week-old human embryo; therefore, causative factors must operate before this. In the developing embryo, the ventral aspect of the primitive foregut is destined to become the tracheobronchial tree. A median laryngotracheal groove develops in the ventral aspect of the foregut of the 23-day-old embryo. As the groove elongates with the growing esophagus, it is postulated that lateral epithelial ridges

fuse to bring about foregut septation. While explaining the possible origins of tracheoesophageal cleft and H-type variant EA fistula, caudocranial separation of the ventral trachea from the dorsal esophagus by a mesenchymal tracheoesophageal septum clearly cannot adequately explain all variants of EA–TEF.

The findings of both an increased number of tracheal rings and a longer trachea in the Adriamycin rodent model of EA–TEF suggest localized abnormal proliferation and elongation of the ventral respiratory component of the common foregut tube. The preferential incorporation of tissue into the trachea may also result in esophageal discontinuity. The association of 13 pairs of ribs with long-gap TEF has also been postulated to strengthen the argument that abnormal forces, in this case hypersomatization, result in a relative deficiency of tissue, which is then preferentially absorbed into tracheal development at the expense of the esophagus.[23]

Further work in the Adriamycin model has also shown that the notochord is implicated with signaling activity to determine the fate(s) of neighboring cell populations. Shh protein, which is expressed in the notochordal tissue, is believed to be pivotal in this dynamic process.[24] Shh stimulates cell proliferation and inhibits apoptosis via intermediary HOX gene expression. Shh binds to the cell surface protein "Patched" (Ptc), which is upregulated by Shh, and thus limits the inductive capabilities of Shh. Ventral misplacement of the notochord may also result in an abnormal diffusion gradient for Shh and a localized imbalance of proliferation and apoptosis in the primitive foregut.

ASSOCIATED ANOMALIES

Associated anomalies are seen in over 50% of newborns presenting with EA and TEF.[2,25,26] Although some of these are relatively insignificant, a high proportion are life-threatening contributing directly to the morbidity and mortality of this condition. The assessment of the newborn with EA–TEF should be prioritized with some urgency to address social, ethical, and surgical strategies relating to the coexistent anomalies. The incidence of such anomalies appears to be highest in babies with pure EA without fistula and infants with orofacial cleft defects.[27] Patients born with EA–TEF have a higher incidence of prematurity than that seen in the normal healthy population. Congenital heart disease (27%) is the commonest comorbid condition and has the greatest impact on survival. Aortic arch anomalies have been shown to occur frequently with "long-gap" EA–TEF variants. Other malformations include urogenital (18%), skeletal (12%), anorectal (12%), and gastrointestinal defects (9%), most notably duodenal atresia. The spectrum of associated anomalies encountered in 581 EA patients treated at Alder Hey Children's Hospital over four decades is shown in Table 46.2.

Several phenotype variants have been described with EA–TEF babies. The VATER association,[27–28] now better referred to as the VACTERL sequence, is defined by the presence of three or more anomalies. In a study from Alder Hey Children's Hospital, Liverpool, VACTERL associations were recorded in 19% of cases.[26] CHARGE association refers to coloboma, heart disease, atresia choanae, retarded development, genital hypoplasia, and ear deformities with deafness. EA–TEF is also apparent in the SCHISIS sequence—exomphalos, neural tube defects, cleft lip palate, and genital hypoplasia.[29–31]

Table 46.2 Abnormalities associated with esophageal atresia and TOF (Liverpool series 1953–1997)

Type	1953–1997 (581 cases)
Cardiac	154 (27%)
Urogenital	105 (18%)
Skeletal	71 (12%)
Vertebral	64 (11%)
Anorectal	67 (12%)
Gastrointestinal	53 (9%)
Palate/laryngotracheal	44 (8%)
VACTERL	25 (19%)

Interestingly, babies with EA and TEF have a higher than expected incidence of hypertrophic pyloric stenosis.[32] The almost universal association of GER with EA may lead to delay in diagnosis if gastric outlet obstruction is not suspected from pyloric stenosis. Tracheomalacia of variable severity is present in EA cases, although the full spectrum of associated tracheobronchial and pulmonary abnormalities deserves further closer scrutiny. Significant anatomical tracheobronchial variant anomalies can be seen in 47% of infants undergoing bronchoscopy.[33] Pulmonary agenesis, foregut duplication cysts, congenital cystic adenomatoid malformations, and sequestered lobe have all been described in association with EA and TEF. Other rare foregut pathology such as laryngotracheoesophageal cleft and congenital esophageal stenosis may coexist with EA and TEF.

ANTENATAL PRESENTATION

Fetal diagnosis is now possible in cases of EA and TEF.[34] This may be clearly advantageous, as delivery can be planned at or near a specialist center with full neonatal surgical capability. Counselling is essential by a multidisciplinary team (obstetrician, pediatric surgeon, neonatologist), and a careful search screen for associated chromosomal or cardiac anomalies is important. The identification of a chromosomal abnormality may have potential implications for termination of pregnancy. Antenatal diagnosis of EA should theoretically reduce the likelihood of inadvertent newborn feeding and aspiration pneumonitis. Despite potential advantages of antenatal diagnosis, it is noteworthy that fetal ultrasonography selects an "at-risk" group of infants with a significantly worse prognosis.[35,37] Perinatal mortality (excluding termination of pregnancy) in a study from Newcastle, UK was reportedly

21%.[35] The classical sonographic features of EA and TEF in the fetus are absence of the stomach bubble and associated polyhydramnios.[36] Prenatal detection rates vary widely in fetal medicine centers (9%–24%), and there also appears to be a high rate of false-positive scans. Approximately 50% of all suspected cases on fetal ultrasound scanning are later proven not to have EA after birth.[35]

CLINICAL PRESENTATION AND DIAGNOSIS

Newborns with EA have difficulty clearing saliva. Episodes of coughing, choking, and transient cyanosis may be observed shortly after delivery. These may go unnoticed, and early attempts to feed the infant result in immediate respiratory distress. Diagnosis is readily confirmed by the failure of passage of a firm nasogastric tube. A characteristic resistance is felt at the blind-ending upper esophageal pouch, and the tube cannot be introduced into the stomach. A plain x-ray, which should include the chest and abdomen, demonstrates the nasogastric tube coiled in the upper pouch. An associated TEF is confirmed by the presence of gas-filled intestinal loops below the diaphragm (Figure 46.2). In isolated or pure EA, a featureless gasless abdominal x-ray is observed (Figure 46.3). The presence of a double bubble on the abdominal plain film is highly suggestive of associated duodenal atresia (Figure 46.4). A careful and thorough search for associated abnormalities is mandatory, specifically checking for imperforate anus also. The cardiovascular system should be examined thoroughly to exclude

Figure 46.2 Chest x-ray film of a neonate with EA and TEF. Note the nasogastric tube coiled in the blind-ending upper esophagus. Air outlining intestinal loops below the diaphragm confirms the existence of a distal TEF.

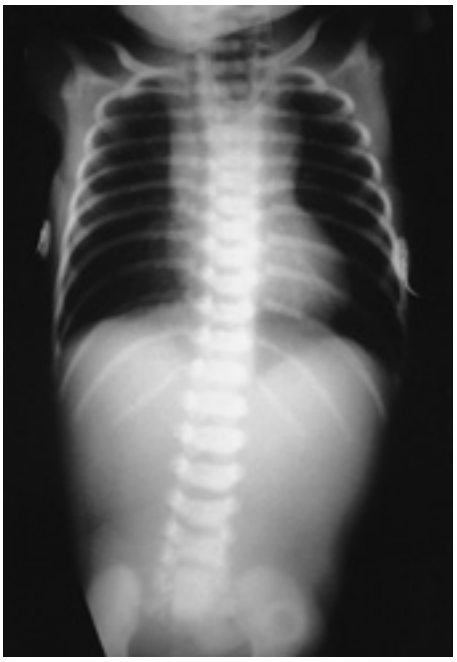

Figure 46.3 Case of "pure" EA without fistula. The nasogastric tube is lying coiled in the upper esophageal pouch. Absence of air-filled abdominal intestinal loops suggests that there is no distal esophageal fistula.

Figure 46.4 EA and TEF with duodenal atresia. Nasogastric tube coiled in upper pouch. "Double-bubble" appearance confirms duodenal atresia.

a major congenital heart defect whose treatment may take higher priority over correction of the EA defect.

Having established the diagnosis, intravenous fluids are commenced and a Replogle sump suction catheter is introduced into the upper esophageal pouch to allow continuous

aspiration of salivary secretions.[38] Alternatively, the upper pouch and oropharynx should be cleared of secretions by frequent intermittent suction. The infant is nursed in the supine or lateral position. Arrangements should be made for early transfer of the newborn to a specialist neonatal surgical unit. Surgery is ideally performed within the first 24 hours following birth in an otherwise healthy baby, as pneumonitis is an ever-present risk from aspiration of saliva and reflux of gastric contents through the lower pouch TEF.

Following admission to the newborn surgical unit, the infant should be fully reexamined and radiology reviewed. The x-ray study may be repeated with gentle downward firm pressure on the Replogle tube. On rare occasions, a fine nasogastric tube may coil in an otherwise normal patent esophagus, and the successful passage of a Replogle tube into the stomach prevents erroneous diagnosis and an unnecessary surgical operation. When EA is diagnosed in a newborn, an estimation of the length of the blind upper esophageal pouch on plain film radiology can give the surgeon useful clue(s) as to the ease or difficulty of a primary anastomosis. Echocardiography should be performed prior to surgery as this will alert the surgeon and the anesthetist to an underlying cardiac defect that may adversely influence prognosis, and may importantly dictate the operative approach by identifying the side of the aortic arch. Blood should be taken for cross-match and a hematological and biochemical profile arranged preoperatively. Broad-spectrum antibiotics should be administered and intravenous fluids continued. Other investigations, notably whole-spine x-rays and renal and cranial ultrasonography, can be deferred until after surgery. Contrast studies of the upper pouch to identify a rare upper pouch fistula have been superseded by preoperative bronchoscopy.

SURGICAL MANAGEMENT

Surgery for EA is now usually performed as an elective procedure.[39] Emergent operation rarely benefits the baby unless the surgeon is confronted with a "high-risk" ventilated newborn with severe respiratory distress and massive gastric distension with impending perforation, where urgent transpleural fistula ligation is lifesaving (see later). It is common practice for most surgical units to advocate bronchoscopy after induction of general anesthesia when planning elective repair of EA and TEF. We now deploy flexible miniature bronchoscopy with instruments of 2.2 mm caliber (Olympus) that can be steered through the endotracheal tube. Bronchoscopy allows precise confirmation of diagnosis and, in most cases, will demonstrate a common variant fistula just proximal to the carina. Occasionally, the fistula may be seen arising at the level of the carina or from one of the main bronchi. A careful and thorough search should be made to exclude an associated upper pouch fistula. The larynx should also be examined to exclude a laryngotracheoesophageal cleft.

Following bronchoscopy, the infant is positioned for operation. In the classical operation, a right thoracotomy is planned with the baby in a lateral position, with the right arm raised across the head so that the scapula can be easily manipulated (Figure 46.5). The surgeon may find a working headlamp and optical loupe magnification greatly facilitate the operation. A curved skin crease incision is made 1 cm below the angle of the scapula, with a muscle sparing thoracotomy. Bianchi et al.[40] have described an axillary skin crease incision, which gives excellent cosmesis, which we increasingly deploy at Alder Hey (Figure 46.6). A retractor is used to lift the scapula off the chest wall, and the ribs are counted downward from the second interspace. The thorax is then carefully entered through the fourth interspace with bipolar diathermy to separate the intercostal muscles to the level of the parietal pleura. The pleura is then gently freed from the ribs to commence the extrapleural dissection and locate the TEF. This procedure is usually started with moist pledgets and, having developed the plane, may be continued by inserting a moistened gauze swab into the extrapleural space, sweeping the pleura away from the chest wall superiorly and inferiorly. Exposure is improved by introducing a Finochettio retractor for rib retraction. Great care is required with the dissection as it is particularly easy to create a pleural tear in the anterior aspect of the incision. If a significant pleural tear occurs during the dissection, it is probably wise to convert to a transpleural approach. The practical advantages of the extrapleural over the transpleural approach include the possibility of avoiding chest drain insertion and, in the event of an anastomotic leak, the potential containment of any leak/soiling within the extrapleural space. The extrapleural exposure is completed by retracting the posterior mediastinal pleura forward with a malleable retractor until the azygos vein is clearly visualized as it enters the superior vena cava in the depths of the wound.

The azygos vein is mobilized and controlled with vascular sloops. The author advocates temporary occlusion of the vein before ligation, as venous return to the heart may rarely be critically dependent on the azygos system. Provided this maneuver does not affect cardiac output, the azygos vein may be safely ligated and divided as it enters the superior vena cava. Alternatively, some surgeons elect to preserve the azygos vein.[41] Once divided, the site of the TEF communication between the trachea and the distal esophagus is usually apparent. Having confidently identified the distal esophagus, a vascular sloop is carefully passed around it. Traction on the sloop controls the fistula and enables its junction with the trachea to be located precisely. Although it is possible to suture ligate the fistula, the author prefers to divide the fistula in stages and apply interrupted 5-0 or 6-0 monofilament prolene sutures to the tracheal component of the fistula. The distal esophagus is secured with a stay suture. The integrity of the TEF repair is evaluated by instilling saline into the thoracic cavity and requesting the anesthetist to exert positive airway pressure to ensure that no air bubbles leak from the suture line. Rarely difficulty may be

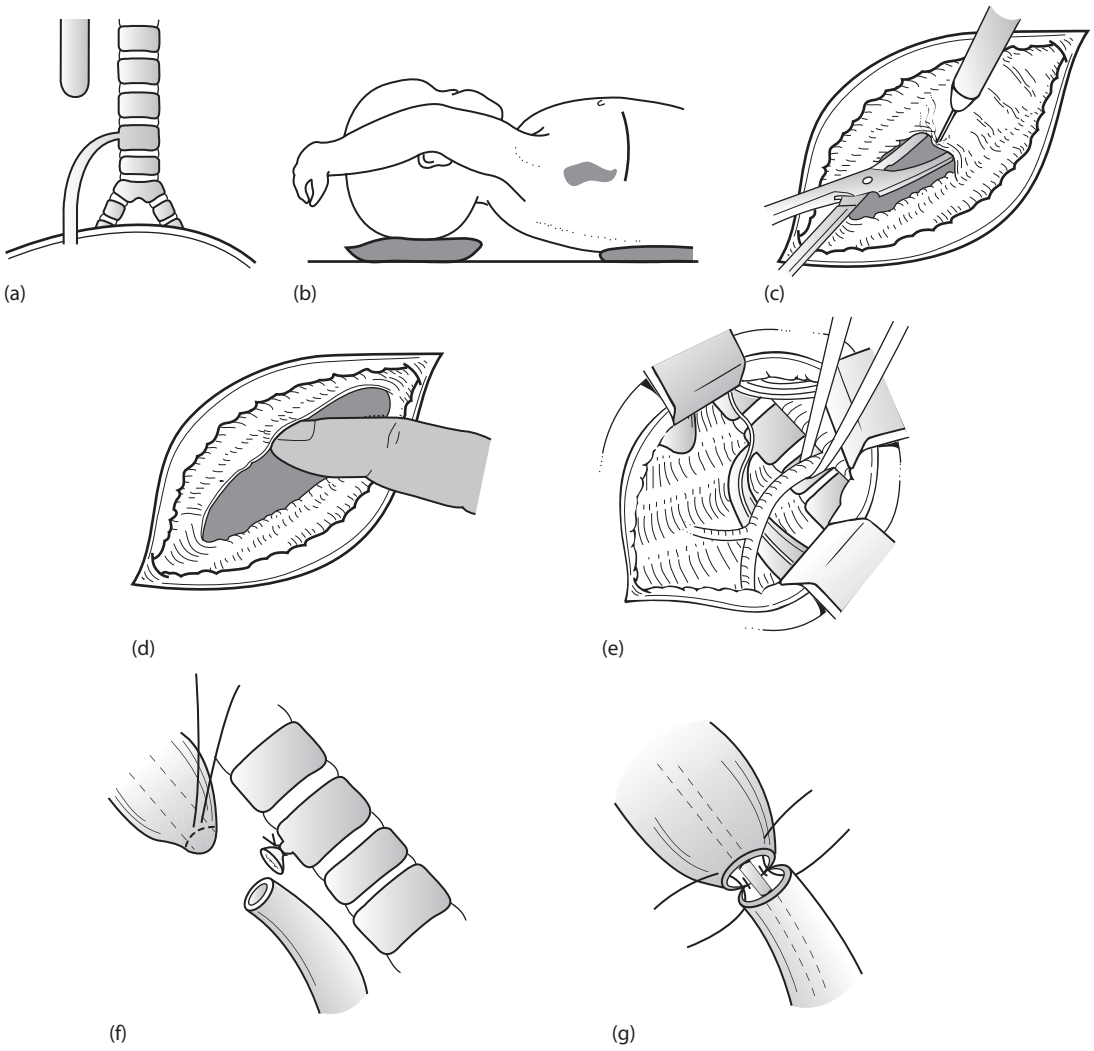

Figure 46.5 **(a)** Most frequent tracheoesophageal anomaly. **(b)** Infant in lateral position prior to operation. Location of skin incision indicated. **(c)** Exposure of intercostal space with muscle dissection. **(d)** Commencement of gentle stripping of parietal pleura from chest wall to develop extrapleural space. **(e)** Operative field when pleura and lung have been retracted medially. The azygos vein is easily seen. The other structures, i.e., the blind proximal esophageal pouch and the fistulous distal esophagus, with vagal fibers lying on its surface exposed. **(f)** Fistula ligated and divided flush with trachea. **(g)** Lateral and posterior sutures and transanastomotic tube in place.

Figure 46.6 Axillary skin incision after EA–TEF repair.

encountered in locating the distal esophagus, and it is quite possible to mobilize the descending aorta in the erroneous impression that it is the esophagus. The surgeon should recognize the distal esophagus by following the vagus nerve as it courses distally, and by observing its rhythmic distension in time with ventilation.

Attention is then focused on the upper pouch—a bulbous structure—which is identified by requesting the anesthetist to push firmly on the Replogle tube. The upper pouch should be secured with a transfixion suture driven through the Replogle tube, which can then be used for traction during mobilization of the upper pouch. Bipolar diathermy is ideal for the mobilization, which should proceed to the thoracic inlet unless the gap separating the esophageal segments is short. Dissection of the plane between the upper pouch and trachea often requires great care to avoid injury

to the trachea. An upper pouch fistula may be identified at this stage and should be repaired with a 5-0 or 6-0 series of interrupted nonabsorbable prolene sutures. The esophageal defect is then closed with 5-0 or 6-0 interrupted absorbable polydioxanone (PDS) sutures. Following adequate mobilization of the upper pouch, it is usually then possible to judge whether a primary anastomosis will be feasible. In most cases of EA with distal TEF, a primary anastomosis is achieved, although occasionally considerable tension is required to complete the repair.

The upper pouch is opened at its most distal extremity. The posterior wall of the anastomosis is commenced by placing two 5-0 or 6-0 PDS sutures through all layers of the lateral margins of the distal esophagus, taking great care to avoid excessive tissue handling and trauma with fine forceps. Sutures are completed by including all layers of the corresponding aspect of the upper pouch taking mucosa so that the knot comes to lie on the inside. Additional posterior wall sutures are inserted. All sutures are individually tied, drawing the esophageal ends together, commencing first with the laterally placed sutures. Having completed the posterior wall of the anastomosis, a 6–8 Fr. fine bore nasogastric tube (TAT tube) is passed by the anesthetist through the infant's nostril to the suture line, where it is grasped by the operating surgeon and carefully positioned distally along the lower esophagus into the stomach. The anterior layer of the anastomosis is completed by placing sutures with knots lying on the outside. When the gap defect length is proven to be wide, primary anastomosis may be facilitated by creating a Livaditis (1969) myotomy on the upper pouch or with an esophageal flap as described by Gough. Anastomosis created under tension requires a chest drain. For straightforward extrapleural primary EA–TEF repair, a chest drain may be unnecessary.[42] Ribs are loosely approximated with absorbable pericostal sutures, and closure of the chest wall/skin is then performed. A chest drain (if present) should be attached to underwater drainage. The baby is transferred to the intensive care unit for ventilatory support and postoperative monitoring. Should additional surgical pathology be present, such as duodenal atresia or imperforate anus, these should be dealt with accordingly under the same anesthetic in the stable infant.

Long-gap EA with distal TEF

The surgeon will encounter situation(s) where the gap between the upper pouch and the distal esophagus is clearly too wide to permit a primary anastomosis after division of the fistula with full mobilization of both the proximal and distal esophagus. Under such circumstances, it is probably wise to proceed to cervical esophagostomy as a "spit stoma" and feeding gastrostomy, accepting the need for esophageal replacement surgery at a later date.[2]

Right-sided aortic arch

Opinion is divided among pediatric surgeons regarding the optimal surgical strategy for management of patients with EA–TEF when a right-sided aortic arch (RAA) is encountered. The incidence of RAA in association with EA is 1.8%–2.5%.[43,44] Chest x-ray may provide some clues. Preoperative echocardiography is at best 20% accurate in identifying this anomaly.[43,44] If the surgeon's suspicion remains high, magnetic resonance imaging should be arranged for definitive diagnosis. If a right-sided arch is identified from preoperative studies, experience from specialist centers advocates left thoracotomy. More commonly, the surgeon will encounter the anomaly unexpectedly in the course of an EA–TEF operation. The presence of a right-sided arch does not preclude a successful anastomosis in this situation, but the procedure is significantly more challenging as is evidenced by the 42% leak rate reported from Great Ormond Street Children's Hospital, London.[45] A trial dissection, including repair of the fistula, via right thoracotomy is appropriate, with completion of the esophageal anastomosis if this seems technically feasible.[46] Where significant difficulty is encountered with the dissection in preparation for the esophageal anastomosis, left thoracotomy is advisable following the division of the fistula through the right or left chest as circumstances dictate. The second thoracotomy may be performed immediately or delayed, depending on the stability of the infant and the experience of the surgeon.

PREMATURE INFANT WITH RDS

In premature very low birth weight (VLBW) babies with lung immaturity, emergency surgery is undertaken when adequate ventilation is compromised by the TEF with abdominal distension and diaphragmatic splinting. The surgical priority here is urgent ligation of the fistula deploying a transpleural thoracotomy to locate the TEF. Should the infant's condition stabilize sufficiently after TEF repair, primary anastomosis of the esophagus may then be appropriate. Otherwise, delayed repair of the esophagus is undertaken when the baby is physiologically stable at a later date. Sudden collapse with stomach wall perforation is equally also a "high-risk" event in fragile VLBW babies. In such situations, emergent ligation of the fistula is lifesaving. Needle paracentesis to relieve tension pneumoperitoneum with laparotomy, repair of the gut perforation, and feeding gastrostomy should follow.[47,48]

POSTOPERATIVE CARE

The infant should be nursed in the intensive care unit following repair of EA–TEF. Weaning from ventilation need not be unduly prolonged in the stable infant with a satisfactory anastomosis. Where the anastomosis is under considerable tension, elective paralysis and ventilation for a period of 3–5 days is practised.[49] It must be conceded, however, that there is no evidence base to support the claim that this technique favorably influences anastomotic healing.[50] There are some experimental data indicating that the level of tension in the anastomosis correlates with the severity of GER.[51] It is the current authors' practice to commence all patients on H_2-antagonists (e.g., ranitidine) as prophylaxis against

anastomotic stricturing potentiated by GER. A contrast esophagogram is optional at the discretion of the surgeon after 5–7 days to evaluate the anastomosis, although major anastomotic leaks are clinically evident before this time. Minor "radiological" leaks are often seen on postoperative contrast studies. These are of no clinical significance and do not preclude the infant from being offered feeds.[52] In most cases, TAT tube feeding can be commenced after 48 hours and slowly increased as tolerated by the infant.

SURGICAL MANAGEMENT OF ISOLATED ("PURE") EA

The diagnosis of isolated EA without fistula is confirmed by the inability to pass a nasogastric tube with a featureless "gasless abdomen" on plain film radiology (Figure 46.3). The absence of intestinal gas below the diaphragm, however, does not always completely exclude the presence of a distal fistula, as a small proportion of babies may have a thin fibrotic connection between the lower pouch and the trachea, which does not readily permit the passage of air.[48]

Surgical management of these newborns is equally challenging and controversial. Many pediatric surgeons consider delayed primary anastomosis of the native esophagus the optimum approach. This strategy demands meticulous nursing care with regular suctioning of the bind ending upper esophageal pouch, chest physiotherapy, and careful attention to nutrition by supervised gastrostomy feeding. A prolonged period of hospitalization (6–12 weeks) is required to achieve this objective. Delayed primary esophageal anastomosis is also associated with its own attendant morbidity with further ongoing care required to manage esophageal strictures and significant GER.[53,54] The desire to preserve the infant's esophagus must be counterbalanced by the humility of knowing when to accept defeat and to abandon the esophagus in favor of a replacement procedure. A feeding gastrostomy is created by minilaparotomy with attention taken to avoid injury to the small stomach of these vulnerable babies with placement of the G-tube.[55] We do not advocate assessment of "gap length" at the time of this operation, deferring to a later session when the baby is more stable.

After a period of approximately 3 weeks, the extent of the gap defect can be assessed by fluoroscopy (Figure 46.7). A radiopaque tube is advanced into the upper pouch and either (1) contrast is instilled via the gastrostomy or (2) a metal sound is introduced through the gastrostomy site directed toward the hiatus and distal esophageal stump. This procedure can be repeated at 2–3 weekly intervals to assess whether the ends of the esophagus are sufficiently close to schedule delayed primary anastomosis.[56] Flexible endoscopy (under general anesthesia) can also be performed after several weeks when the G-tube tract site is mature by steering the "baby scope" to locate the blind esophageal stump. Images taken "on table" likewise provide an accurate gap length assessment with a radiopaque tube placed in the upper pouch. A distance of less than two vertebral bodies separating upper and lower pouches is ideal. However, in practical terms, there is little to be gained by the surgeon when delaying restorative surgery beyond 12 weeks of age.

Figure 46.7 Gap assessment in a case of pure EA. The scale bar represents gap length (cm).

The operation of delayed primary anastomosis essentially involves the same meticulous approach by the surgeon. It is to be expected that the anastomosis may be created under considerable tension. The upper pouch should be fully mobilized to the thoracic inlet. The distal esophagus is frequently a primitive stump and not readily identified at thoracotomy without the use of special aids. The surgeon can readily facilitate the location of the distal esophageal stump by passing a flexible endoscope via the G-tube tract site toward the esophageal hiatus. A brightly illuminated stump is easily identified in the depths of the thoracotomy wound. A stay suture (5-0 or 6-0 prolene) should be secured on the distal esophageal segment to aid its mobilization and dissection. Some surgeons still prefer passing metal bougies to identify the distal esophagus. The distal esophagus may be dissected to the diaphragmatic hiatus to help reduce tension on the anastomosis. A Livaditis myotomy or upper pouch flap may also be helpful.[57–61] The author prefers to perform a Livaditis myotomy over the inflated balloon of a Foley catheter passed by the anesthetist per orally to the upper pouch. Extra length can also be obtained by proceeding to laparotomy and creating a myotomy on the lesser curve as described by Scharli or a Collis gastroplasty.[57–61] If a primary anastomosis is still not possible using these techniques, the options are then to proceed cervical esophagostomy and schedule an esophageal replacement procedure when the infant is 18 months or older. A decision to convert to an immediate replacement of the esophagus is equally feasible provided that the surgeon and the team are sufficiently skilled. However, caution should be exercised when offering

replacement to very young infants as risks of recurrent pulmonary aspiration are not insignificant in this age group before walking and upright posture is established. Options for esophageal replacement include gastric transposition, reverse gastric tube, colon replacement, and jejunal interposition.[2,64] Gastric transposition and colon graft interposition are currently the most popular operations.

Delays in restoring esophageal continuity have significant drawbacks. Firstly, there is the ever-present risk of aspiration pneumonitis, and secondly, the inability to feed the infant via the normal oral route. Although the child's nutritional needs are met by gastrostomy feeding, the inability to establish oral feeds may lead to long-term feeding and speech problems. Spitz has recommended formally assessing the length of the gap when the gastrostomy is initially performed. A gap length >6 vertebral bodies (6 cm) would prompt him to abandon the esophagus and perform a cervical esophagostomy.[64] This approach of early cervical esophagostomy and delayed esophageal replacement permits early sham feeding, which theoretically promotes neuronal maturation and development of the learning skills needed for feeding and later speech acquisition.

A number of other innovative approaches to the operative treatment of long-gap EA have been described. True primary repair has been performed with reported gap lengths exceeding 5 cm. The hypothesis tested by Foker et al.[65] was that a well-constructed esophageal anastomosis can withstand considerable tension. The value-added technique for esophageal reconstruction (VATER) operation involves mobilizing the gastric fundus and performing a limited Thal fundoplication. At thoracotomy, the proximal stomach is drawn into the chest, and a primary esophageal anastomosis is performed.[66] Staged neonatal colon esophagoplasty has also been described, which involves the isolation of a short length of transverse colon based on the ascending branch of the left colic vessels at the time of open gastrostomy.[67] The conduit is positioned transhiatally in the posterior mediastinum to be retrieved at thoracotomy several days later when continuity is restored.

Several well-established operations are available to restore gastrointestinal continuity in long-gap EA, where the infant's own esophagus has been abandoned.[64] Colon replacement was originally popularized by Waterston. The colon conduit may be isoperistaltic (left colon based on the left colic vessels) or anteperistaltic (right colon based on the ileocolic vessels). The colon is best routed via the posterior mediastinum (via the hiatus) or through right or left chest cavities to the neck. Cervical esophago-colon anastomosis is prone to leakage. Colon grafts also tend to dilate, and kinking is not uncommon due to tortuosity. Respiratory problems are seen due to recurrent aspiration as the new food pipe created with colon is "nonrefluxing."

The stomach may be used to create an esophageal substitute graft. A gastric tube esophagoplasty can be fashioned from the greater curvature of the stomach, based on the left gastroepiploic (anteperistaltic) or right gastroepiploic arcades (isoperistaltic), preferentially using the posterior mediastinum as a route to the neck anastomosis.[68] The long suture line of the tube created and the greater curve suture line are susceptible to bleeding and leaking. Reflux is a problem and can predispose to anastomotic stricture formation. However, dilatation and kinking are not encountered with the graft. GER may be controlled by performing a posterior partial wrap fundoplication.

Gastric transposition has been advocated by Spitz and has the merit of simplicity.[64,69] The vascular supply is based on the right gastric and right gastroepiploic vessels, which allows full mobilization of the greater and lesser curvatures. After pyloroplasty, the stomach is passed through the mediastinum via the diaphragmatic hiatus and the esophagogastric anastomosis completed in the neck. Leakage from the anastomosis is reported in some 12% of cases and strictures requiring periodic dilatation in a similar percentage of patients.[69]

Jejunal orthotopic interposition grafting reemerged as a useful technique for esophageal replacement following encouraging case series reports from the Netherlands by Klaus Bax and colleagues almost a decade ago.[70] Jejunal grafts do not dilate excessively and retain good peristalsis, which may explain why GER does not appear problematic for some of the patients.[70,71] Use of jejunal substitutes has declined with gastric transposition and colon grafts being by far the choice of many surgeons worldwide today.

H-TYPE TEF

H-type TEF comprises 4% of all EA–TEF variants.[2] It is perhaps more accurately termed N-type fistula as the track runs obliquely from trachea to esophagus. Infants with H-type TEF usually present within the first month after birth, with a characteristic history of choking with feeds and cyanotic spells. Gross abdominal distension mimicking intestinal obstruction is an occasional presenting feature, which we have encountered as the belly "accumulates wind" from the fistula communication. Older children may have frequent chest infections with recurrent right upper lobe pneumonia(s) due to chronic aspiration.

Diagnosis may be readily established by a dynamic prone video esophagogram (Figure 46.8). In this study, contrast is injected through a nasogastric tube, which is slowly withdrawn from the esophagus. However, H-type fistula(e) may be missed in approximately 50% of contrast studies. Where suspicion remains, bronchoscopy should be scheduled. At bronchoscopy, a size 4 Fr. ureteric catheter is passed through the fistula into the esophagus to facilitate identification during subsequent neck dissection. A nasogastric tube is passed into the stomach, and broad-spectrum antibiotics commenced. A right transverse skin crease incision is marked a finger's breadth above the clavicle, before positioning the neck in extension with a sandbag placed under the shoulders. The sternomastoid is retracted laterally and, if necessary, its sternal head divided. The carotid sheath is mobilized after division of the middle thyroid vein. The ipsilateral recurrent laryngeal nerve should be identified and carefully preserved.

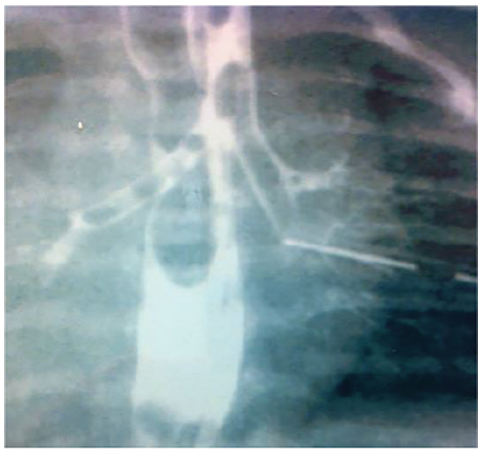

Figure 46.8 Tube esophagogram study showing H-TEF.

Intraoperatively, we have found that flexible bronchoscopy with a 2.2 mm caliber instrument (Olympus) can aid precise identification by brightly illuminating the site of the fistula tract (Figure 46.9).[72] The esophagus is carefully dissected at this point and slung with vascular sloops both above and below the fistula. Caution should be taken with dissection as the contralateral recurrent nerve is also vulnerable to injury at this point. Traction on the esophagus enables the fistula to be secured with stay sutures. After withdrawing the ureteric catheter (and 2.2 mm bronchoscope if deployed), the fistula is divided and the tracheal component repaired with 5-0 or 6-0 interrupted nonabsorbable prolene sutures. The esophagus is closed with 5-0 or 6-0 PDS sutures. Some surgeons recommend tissue interposition between esophageal and tracheal suture lines to prevent recurrent fistula.

The infant should remain intubated and ventilated in the early postoperative period, as tracheal edema can result in progressive stridor.[73] The vocal cords should be checked on extubation, given the significant risk of recurrent nerve palsy. Nasogastric tube feeding may commence after 48 hours, and oral feeds may be slowly introduced thereafter.

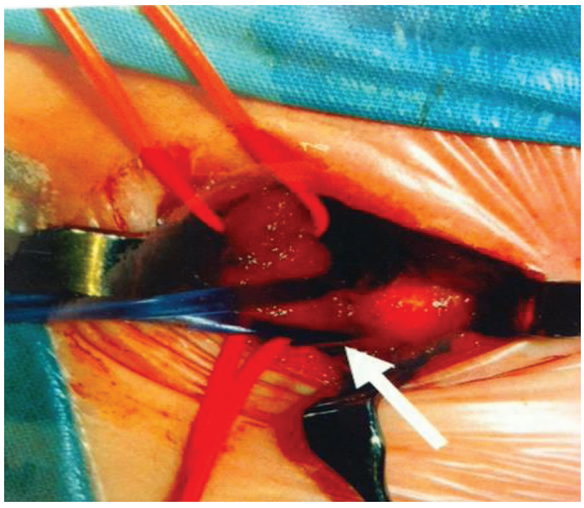

Figure 46.9 Operative photograph showing a 2.2 mm flexible bronchoscope brightly illuminating an H fistula tract—(fistula marked with arrow). Sloops secure the mobilized esophagus exposing the dissection plane between trachea and esophagus with H fistula.

The Nd:YAG laser has also been successfully used to treat congenital H-type TEF. Repeated short-duration pulses of laser light are used to coagulate the fistula.[74] Despite some success with this approach, the technique has not gained widespread acceptance, and open repair remains the gold standard.

EA–TEF—COMPLICATIONS AND SPECIAL CONSIDERATIONS

Anastomotic leak

The incidence of anastomotic leak following repair of EA and TEF ranges from 11% to 21%.[48,75] This is usually manifested by pneumothorax and salivary drainage from the chest drain. It is rare for the anastomosis to be completely disrupted. Provided that a transanastomotic tube is in place, it is usually possible to control the leak with an adequately sized chest drain. With adequate drainage, broad-spectrum antibiotics, and total parenteral nutrition, the esophagus will usually heal, although a prolonged period with a chest tube may be necessary. Some surgeons have used hyoscine patches in an attempt to "dry up" the salivary leak. Others advocate early re-exploration (<48 hours), with direct repair of the esophagus if possible, and the establishment of satisfactory drainage where a major leak is suspected.[13,75,76] When conservative management fails with uncontrolled sepsis, the establishment of a cervical esophagostomy and a feeding gastrostomy are essential. The child is committed to esophageal replacement at a later date. A clinical anastomotic leak predisposes to the development of an esophageal stricture.[77] While this association may seem logical, others contest such a correlation.[75]

Gastroesophageal reflux

GER disease occurs in 40%–50% of children following repair of EA–TEF. GER may cause failure to thrive, can predispose to recurrent aspiration episodes, and may lead to esophagitis and stricture formation.[2] Management of symptomatic GER initially requires aggressive medical therapy. Postural therapy and close attention to feeding regimes, with calorie supplementation, may prove effective management strategies. Feed thickeners (e.g., Carobel), antacid preparations (e.g., Gaviscon), H_2-antagonists (e.g., ranitidine), proton pump inhibitors (e.g., omeprazole), and prokinetic agents (e.g., domperidone) may be used in various combinations if vomiting is significant.

GER may contribute to recurrent aspiration episodes, with frequent symptoms of respiratory distress including tachypnea, apneic episodes, cyanosis, and x-ray evidence of patchy pneumonic changes. The differential diagnosis in this clinical setting also includes swallowing incoordination and respiratory distress from significant tracheomalacia.

It is not uncommon to see infants in whom all of these factors are operating to a variable degree. It is important not to overlook the possibility of a recurrent TEF as a cause of repeated episodes of respiratory distress, although the history of choking and cyanotic episodes during feeding is usually much more evident in infants with a recurrent fistula. The selective use of esophageal pH monitoring, contrast meal, bronchoscopy, and assessment of swallowing by video fluoroscopy may assist in evaluating the contribution of GER and other allied pathologies to respiratory symptoms. Failure to control GER despite full medical therapy is an indication for fundoplication.

Fundoplication rates following surgery for EA vary widely between surgery centers (6%–45%), reflecting the varied enthusiasm for antireflux operations in the clinical setting of GER and esophageal dysmotility.[2,78] There are several reasons for caution when considering fundoplication in EA patients. Dysphagia may be aggravated as a consequence of underlying foregut dysmotility. Fundoplication following EA repair has a higher failure rate (15%–38%) than is generally observed in otherwise normal patients with isolated GER.[79] Some authors recommend a partial wrap (Thal) fundoplication because of the lower incidence of postoperative dysphagia.[78] Despite such concerns, many pediatric surgeons prefer a short (1.5–2.0 cm) 360° floppy Nissen wrap for its proven effectiveness in reducing GER.[79] The high failure rate of fundoplication and the significant complications associated with surgical treatment of GER demand vigilant follow-up in this group of patients.

Anastomotic stricture

Reported definitions of esophageal stricture following repair of EA lack consistency. The incidence of symptomatic strictures requiring dilatation varies from 37% to 55%.[52,77] Some degree of anastomotic narrowing is invariably seen in all postoperative imaging studies, but this is rarely of a sufficient degree to cause symptoms in the early period after operation. Parents should be advised to report symptoms of prolonged feeding, incomplete feeding, or associated respiratory difficulty to clinicians. Contrast studies may be arranged. Such symptoms prompt us to arrange surveillance endoscopy to assess the caliber of the esophageal anastomosis. Balloon dilatation is our preferred method of treating symptomatic strictures. The radial dilating forces generated during balloon dilatation are considered to be less traumatic than the longitudinal shearing forces caused by conventional bougienage.[80,81] Balloon dilatation is performed under fluoroscopic control by passing a guide wire through the stricture, over which a balloon dilator of appropriate size is introduced. Its position is confirmed by partially filling the balloon with contrast medium, so that "waisting" due to the stricture is centrally located (Figure 46.10). The balloon is then maximally inflated using dilute contrast medium to dilate the stricture. A contrast esophagogram is performed after removing the balloon to ensure that there has been no injury perforation. Some surgeons deploy steroid injections

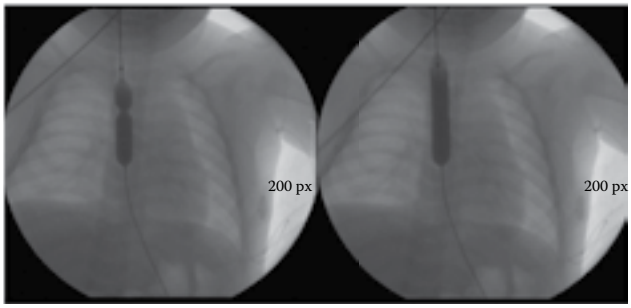

Figure 46.10 Balloon dilatation of an esophageal anastomotic stricture—"wasting" appearance shows the region of stricture.

or mitomycin C to manage stricture(s). A tailored program of surveillance endoscopy/dilatations may therefore be scheduled for some patients. If a stricture requires repeated dilatations, GER should be fully investigated by a combination of an upper GI contrast study, pH study, and endoscopy. Recalcitrant esophageal anastomotic strictures may require resection and fundoplication.

Tracheomalacia

Tracheomalacia is present to a variable degree in all patients with EA. It is thought to be responsible for the characteristically loud "barking" TEF cough.[2] Infants with tracheomalacia demonstrate expiratory stridor, which may result in episodes of desaturation, apnea, cyanosis, and bradycardia (often associated with feeding), and life-threatening so-called "dying episodes." Severe tracheomalacia may be evident in the early postoperative period, when it proves difficult to wean the infant from the ventilator.

Indications of the severity of tracheomalacia include ventilator dependency, respiratory distress characterized by stridor and chronic carbon dioxide retention, and "dying episodes." Full investigation for severe GER and recurrent TEF (see later) is advisable alongside evaluation of tracheomalacia, as aspiration secondary to GER and a recurrent fistula can mimic these symptoms. The extent of tracheomalacia is assessed by bronchoscopy under conditions of spontaneous respiration. The lumen of the trachea is significantly compressed anteroposteriorly and assumes a scabbard-like appearance during expiration due to tracheal cartilage deficiency. A further contribution is often made by the upper esophagus, which may bulge posteriorly into the airway. Tracheobronchomalacia can extend beyond the carina into the main stem bronchi.

As tracheomalacia can be self-limiting, surgical intervention is reserved for patients with life-threatening symptoms.[2] Treatment options include continuous positive airway pressure (CPAP), aortopexy, tracheostomy, and, more recently, tracheal stenting.[82,83] CPAP is a useful temporizing measure but may be required for several weeks. Aortopexy is traditionally performed by anterior left thoracotomy through the third interspace. The left lobe of the thymus is excised to gain access to the root of the aorta

taking care not to damage the phrenic nerve. Plegetted sutures incorporating reinforcing Dacron squares are placed through the adventitia of the aortic root and the ascending aorta. The sutures are passed through the periosteum of the manubrium and tied, hitching the aorta forward, thereby relieving compressive forces on the trachea. Although this operation cannot resolve distal tracheobronchomalacia, it often provides immediate dramatic symptomatic relief. Failure of aortopexy may be an indication for tracheostomy, although some authors advocate tracheal stenting in this situation.[2,82,83]

Recurrent TEF

Recurrent TEF is estimated to occur in 5%–15% of cases.[84] A recurrent TEF may result from an anastomotic leak, but the possibility of a missed upper pouch fistula should always be considered. Symptoms include recurrent chest infections and choking attacks during feeding. A high index of suspicion is required if the diagnosis is not to be overlooked. Chest x-ray may sometimes reveal an air esophogram. The initial investigation of choice is prone video esophagography. If this study fails to demonstrate a fistula and the diagnosis remains strongly suspected, combined esophagoscopy and bronchoscopy should be performed. Rigid bronchoscopy is performed initially, and the site of the original fistula is carefully examined. The fistula is gently probed with a ureteric catheter, and methylene blue is carefully instilled into the fistula pit. Synchronous flexible esophagoscopy is performed to see if blue dye can be seen entering the esophagus. Should this fail to demonstrate the fistula, an "air/water test" is a useful supplementary investigation. The esophagus is filled with water and positive pressure ventilation applied to the bronchoscope. Occasionally, bubbles of air can be seen emanating from the fistulous opening into the esophagus.

Several strategies have been described to deal with the recurrent TEF. The traditional approach is formal repair via right thoracotomy. At bronchoscopy, an attempt should be made to pass a fine ureteric catheter through the fistula into the distal esophagus. A flexible miniature bronchoscope (2.2 mm, Olympus) may be useful to navigate, cannulate, and brightly illuminate the fistula tract. The fistula is repaired using a similar strategy to that deployed for the H-type variant, i.e., isolation/slooping the esophagus repairing the fistula as described earlier. Tissue interposition between suture lines is sometimes advisable in an attempt to reduce the chances of further fistula formation. A 10%–22% risk of refistulation has been reported.[84] Other approaches described to treat recurrent TEF include diathermy fulguration of the fistula tract.[85] This technique has been refined using the Nd:YAG laser to obliterate the epithelial communication. Sclerosing agents, histoacryl, and fibrin glue(s) have all been injected subepithelially to occlude fistulae. A recent review of endoscopic therapies reported an overall success rate of 55% with several sessions required to effect cure. A study from Oxford, however, concluded that formal surgical re-exploration remained the treatment of choice, except in high-risk patients.[86]

EA–TEF ADVANCES

Developments in minimally invasive surgery have now extended to the EA and TEF newborn population. In 2002, Rothenberg[87] reported the technical feasibility of endoscopic repair in a personal series of eight newborns with EA–TEF ranging in weight from 2.1 to 3.4 kg. This study followed the first pioneering operation of EA in a 2-month-old infant in 1998. Collaboration from members of the International Pediatric Endoscopic Surgery Group (IPEG) led to a 2005 multi-institutional analysis of thoracoscopic repair from centers located in the United States, Europe, and Hong Kong.[88] One hundred and four babies with common variant EA and TEF (excluding H-type and long gap without fistula) were included. Of these, there were five (4.8%) conversions to open thoracotomy and a staged repair in one baby due to unforeseen long-gap EA–TEF. Twelve infants (11.5%) developed early leaks and strictures, and 32% required esophageal dilatation(s). Survival in this selected population was 97% with three deaths recorded of which one was directly related to the EA–TEF repair on the 20th postoperative day. Additional operations were required for associated anomalies. These included duodenal atresia repair, imperforate anus surgery, aortopexy, and cardiac procedures. Twenty-five babies (24%) also underwent laparoscopic fundoplication for GER. In 2009, MacKinlay[89] (Edinburgh) reported good outcomes in a study of 26 infants—88% survival, 27% leak rate—all minor not requiring operation and 35% acquired strictures needing dilatation(s). Long-term benefits cited from minimally invasive surgery include a reduction in musculoskeletal morbidity notably winged scapula and unsightly skin scarring. For pediatric surgery centers currently not offering MIS repair, the axillary skin crease incision popularized by Bianchi provides an excellent alternative with good aesthetic outcome and comparable reductions in skeletal morbidity with all the benefits of classical open repair techniques.[40] Surgeon preference for MIS EA–TEF vs. open operation remains widely debated.

QoL AND LONG-TERM OUTCOME

The excellent survival of EA–TEF babies born in the modern era has prompted detailed analysis of morbidity with emphasis on long-term outcomes.[2,90] Several studies have examined respiratory function in EA children.[91–94] Symptoms of asthma and bronchitis are frequent, especially in a young child, and may persist into adolescence. Almost half of all children require future hospitalization due to ongoing respiratory morbidity. In a large Melbourne series comprising 334 EA children, episodes of pneumonia were seen in 31% of children under the age of 5 years, compared with 5% of those over 15 years.[91] The prevalence of annual attacks of bronchitis in these two age groups

was 74% and 41%, respectively, with asthmatic symptoms reported in 40% of patients from each age range.[91] Spirometry studies have demonstrated both obstructive and restrictive abnormalities in over half the patients, and a similar proportion had a maximal working capacity below the normal range.[92] Tracheobronchial inflammation and airway narrowing have been demonstrated by bronchoscopy in one-third of patients, with histological evidence of inflammation in a further third.[93] It is plausible that abnormalities of bronchial anatomy, which are common in EA–TEF, may contribute to respiratory morbidity. Clinical assessment by a respiratory physician with use of prescribed inhalers to manage reactive airway disease and antibiotics/physiotherapy for chest infections is recommended. The contribution of aspiration episodes, whether due to esophageal dysmotility or GER, to respiratory symptoms should be actively investigated. Recognition of the long-term respiratory morbidity associated with EA patients prompted the establishment of a specialist EA–TEF clinic at Alder Hey Children's Hospital, Liverpool almost 20 years ago staffed by pediatric surgeons, respiratory physicians, physiotherapists, and dieticians. This multidisciplinary team approach ensures that vigilant health surveillance is focused on all aspects of the child's welfare including the smooth transition to adult medical/surgical services.[94,95]

Esophageal dysmotility is also a significant factor in long-term patient morbidity.[96] It is clearly implicated in many cases of food bolus impaction when endoscopy reveals no significant anastomotic narrowing. Less severe symptoms of dysphagia have been reported in up to 20% of adolescents[96] and 48% of adults on long-term follow-up. Esophageal manometry and fluoroscopy studies will demonstrate degrees of dysmotility in nearly all patients.[92] The dysmotility associated with EA may reflect intrinsic innervation abnormalities of the esophagus.[97] This may further contribute to respiratory morbidity through repeated "silent" aspiration episodes.

GER may persist into adult life. Symptoms of heartburn and acid brash range from 18% to 50% in long-term follow-up studies.[92,93] Clinical symptoms may underestimate the true incidence of GER as demonstrated by esophageal pH monitoring. An 8% incidence of Barrett's esophagus has been reported.[98,99] The relative risks of esophageal cancer developing in the lifetime of a patient are uncertain, though five cases have been recorded in the world literature.[100,101] These findings further highlight the importance of comprehensive long-term adult follow-up.[95,102]

Various QoL scoring systems have been deployed to evaluate adult populations treated for EA and TEF. Using the Spitzer index and a gastrointestinal QoL index, it has been shown that adults having primary anastomosis as newborns enjoyed an unimpaired QoL. QoL metrics were also more favorable in patients who had native esophageal repair compared to colonic interposition.[90] Psychosocial studies show more learning, emotional, and behavioral difficulties in EA adults than the healthy general population. Cognitive performance(s) were also significantly impaired in a high-risk patient group characterized by associated major congenital anomalies and/or the requirement for prolonged ventilation in the neonatal period.[93, 103]

An energetic support group (TOFS)—a UK-based charity was founded in 1982 for the benefit of children and parents. The organization with over 1000 members (http://www.tofs.org.uk) provides a useful networking group for families together with a valuable handbook—*The TOF Child*.[104] With regular annual conferences attended by health care professionals and families, opportunities therefore exist for knowledge exchange and practical advice. TOFS UK also raises valuable funds for research.[2] Similar support networks exist in other European countries, e.g., KEKS, Germany.

Congenital esophageal stenosis

MASAKI NIO, MOTOSHI WADA, AND HIDEYUKI SASAKI

INTRODUCTION

Congenital esophageal stenosis (CES) is a rare condition. Gross[1] reviewed 38 cases of CES from the records of the Boston Children's Hospital in 1953 and reported that repeated dilatation provided complete relief in most cases; however, he later stated that CES cases who do not respond after six attempts of dilatation should be strongly considered for surgical resection or revision of the strictured area. Since then, a number of treatment modalities have been devised, but there is no consensus regarding which treatment option is the best. Although the efficacy of conservative treatments varies on a case-by-case basis, surgical treatment, which is expected to provide prompt relief of symptoms, carries certain risks of postoperative complications, including leaks, stricture, and gastroesophageal reflux (GER). Surgeons should consider differential diagnoses and understand the pathological basis of CES to be able to employ the most appropriate treatment strategy.

PATHOLOGY

CES is defined as an intrinsic stenosis of the esophagus, caused by congenital malformation of the esophageal wall. There are three pathological types of CES, namely, CES with tracheobronchial remnants in the esophageal wall,[2–16] fibromuscular thickening of the esophageal wall,[11,17–21] and membranous mucosal diaphragm or web.[8,11,22–30]

Stenosis due to tracheobronchial remnants is the most common form of CES; this condition is localized in the distal esophagus.[12] Fibromuscular thickening is observed in the middle or lower portions of the esophagus,[11,21] and membranous webs are observed in the upper or middle portions of the esophagus.[11,26–30] The stenotic area in cases with tracheobronchial remnants is usually localized, and the area of the fibromuscular stenosis varies from one to several centimeters in length, with circular thickening of the esophageal wall. In cases of membranous web, single webs have been observed in children,[26,28,30] whereas multiple webs, referred to as multiple trachea-like rings, have been observed in young adults.[31–33]

In CES with tracheobronchial remnants (mature or immature cartilages), seromucous tracheobronchial glands and ciliated epithelium have been usually observed during microscopic examination of the stenotic esophageal wall (Figure 47.1).[5,11,34] On the other hand, in fibromuscular stenosis, circumferential proliferation of smooth muscle fibers with moderate fibrosis has been observed (Figure 47.2).[11,21,34] Singaram et al.[35] reported a significant reduction of myenteric nitrinergic neurons and fibers in the muscle layer of two young adults diagnosed with the fibromuscular variant of CES. Lack of submucosa,[27] loose vascular connective tissue, and diffuse lymphocyte infiltration[26] have been microscopically observed in specimens of membranous web.

EPIDEMIOLOGY/ETIOLOGY

CES occurs in 1 in 25,000–50,000 live births.[11,36] Although the reason is unknown, the incidence of CES is higher in Japan than elsewhere.[8,37] There is no sex-associated predisposition.

CES caused by tracheobronchial remnants and fibromuscular thickening is thought to be a developmental disorder that arises during the first fetal month. The condition likely occurs during the formation and separation of the primitive foregut into the trachea and esophagus by the end of the first fetal month. The membranous mucosal diaphragm or web is believed to be a result of incomplete reformation of the esophageal lumen upon recanalization of the esophagus between the sixth and eighth week of gestation.

The incidence of anomalies associated with CES is reported to be 17%–33%[11,37]; among these, esophageal atresia/tracheoesophageal fistula (EA/TEF) is the most common,[9–11,18,19,24,37–43] and 3.6%–14% of EA/TEF cases are associated with CES.[41,44–47] Surgeons should be aware of the high incidence of association of EA/TEF with distal CES. Moreover, cardiac anomalies,[11,24] intestinal atresia,[11,23] anorectal malformation,[10,37] and chromosomal anomalies[7,11,21,23] may also be associated with CES.

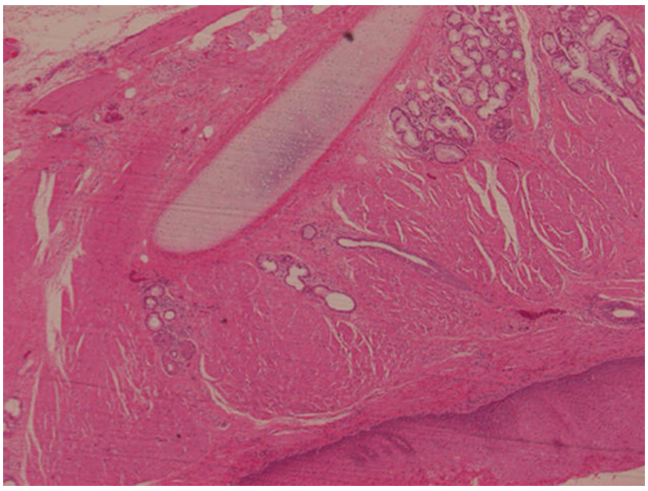

Figure 47.1 CES with tracheobronchial remnants. Mature or immature cartilages, the seromucous tracheobronchial glands and ciliated epithelium are usually seen in CES with tracheobronchial remnants.

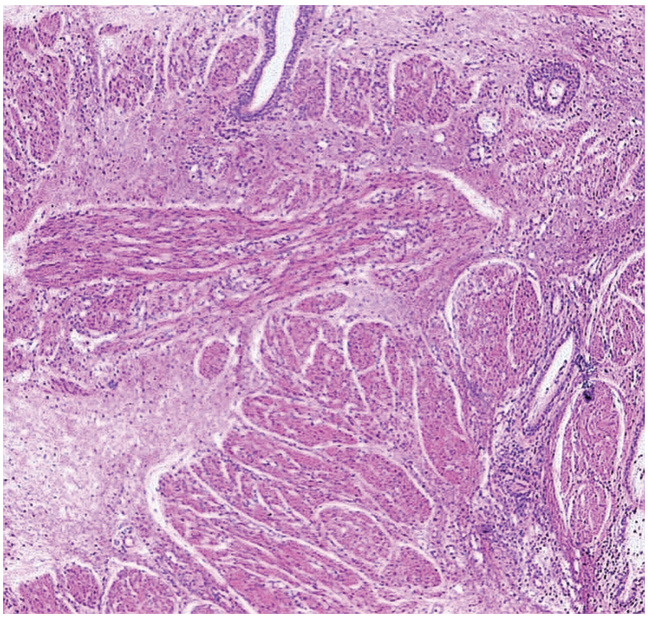

Figure 47.2 Fibromuscular thickening of the esophageal wall. Circumferential proliferation of smooth muscle fibers with moderate fibrosis is seen in fibromuscular stenosis.

SYMPTOMS

Symptoms of CES include vomiting or regurgitation, dysphagia, recurrent respiratory tract infections, and growth retardation. Although the etiology of CES usually has congenital origins, symptoms rarely develop in newborns.[25] Characteristically, the onset of regurgitation coincides with the introduction of semisolid and solid foods around 6 months of age in patients with tracheobronchial remnants.[34] In some patients, a foreign body in the esophagus might be the first symptom observed.[36] When esophageal peristalsis is preserved, the presentation of CES might be delayed until adulthood.[48]

Patients with CES associated with EA/TEF are sometimes diagnosed at the time of surgical repair or during the postoperative course of EA/TEF before presenting any symptoms of CES.

DIAGNOSIS

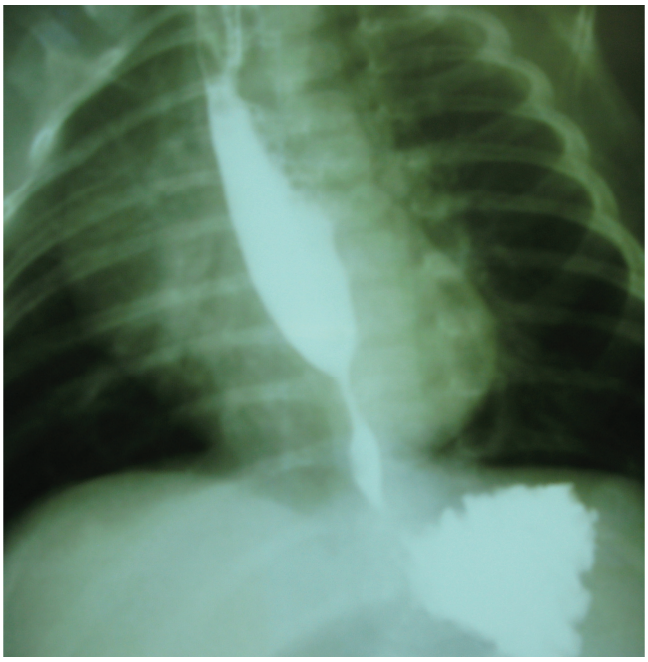
Difficulties in determining the differential diagnoses of CES and being able to distinguish CES from achalasia, from secondary esophageal stenosis, and particularly, from a stricture due to reflux esophagitis[36] have resulted in various clinical problems during treatment of CES. First, achalasia, inflammatory esophagitis, and stenosis caused by a tumor or extrinsic compression of the esophagus should be excluded. The location of the stenosis varies with the type of pathology, as mentioned in the earlier section.

Patients who develop symptoms such as vomiting and dysphagia should undergo a barium swallow test to obtain an esophagogram. Esophagograms of stenoses exhibit tapered or abrupt narrowing of the esophagus with varying degrees of dilatation of the suprastenotic portion (Figure 47.3). Most of the stenoses due to tracheobronchial remnants are visible on esophagograms as abrupt esophageal narrowing, whereas fibromuscular stenoses usually exhibit tapered esophageal narrowing.[41,43] Following surgery of EA/TEF, an esophagogram should be evaluated with great care, as it is easy to overlook a narrowing at the mid-distal esophagus. To evaluate the exact site and extent of the stenosis, fluorography using a balloon catheter can be used. The balloon catheter is inserted through the esophagus, and the location and shape of the inflated balloon provide a clear image of the esophageal stenosis (Figure 47.4).

Esophageal endoscopy (i.e., esophagoscopy), manometry, and pH monitoring are helpful tools for obtaining differential diagnoses when trying to distinguish CES from achalasia and secondary esophageal stricture due to GER. Esophagoscopy can directly evaluate the stenotic area and the site of the gastroesophageal junction, as well as the presence and severity of esophagitis. The mucosa distal to the stenosis is normal in CES. In addition to esophagoscopy, endoscopic ultrasonography has recently been employed to evaluate the fine structure of CES. It is also useful for determining a treatment strategy, which may be either balloon dilatation or surgical treatment.[42,49,50] According to a systematic review by Terui et al.[51] endoscopic dilatation is recommended as the primary therapy for CES, except for patients with tracheobronchial remnants.

In CES cases, preoperative esophageal manometry demonstrates a normal pattern of the lower esophageal sphincter and a small high-pressure zone in the resting pressure profile, which corresponds to the stenotic area of the esophagus. Impaired esophageal motility is commonly observed in CES patients.[52,53] Further, pH monitoring can reveal a significant positive reflux, which is not observed in patients with CES, unlike in patients with GER.

(a)



(b)

Figure 47.3 Esophagograms of CES. An abrupt **(a)** or tapered narrowing **(b)** of the esophagus evident on an esophagogram.

CES associated with EA/TEF is often overlooked at the time of the initial esophageal surgical repair and is typically only diagnosed later. Ibrahim et al.[54] reported taking a surgical specimen routinely for histopathological studies from the tip of the lower esophageal pouch during primary repair of EA/TEF.

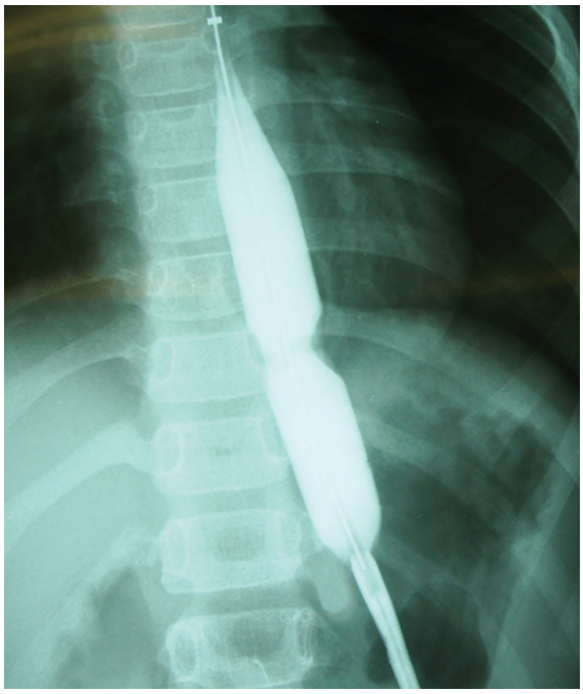


Figure 47.4 Fluorography using a balloon catheter. A low-compliance balloon catheter (RigiflexTM II, Boston Scientific Ltd, UK) is placed at the stenosis and gradually inflated, and then the location and the length of the stenosis are clearly visible.

TREATMENT

The principal aims of CES treatment include the alleviation of symptoms and maintenance of the antireflux mechanism of the gastroesophageal junction. This condition can be treated either conservatively (by nonsurgical methods) or by surgical intervention. Nonsurgical methods include balloon dilatation and endoscopic treatment.

Nonsurgical treatment

Balloon dilatation is the first choice of treatment for CES. This method should be employed in patients with tapered esophageal narrowing and abrupt esophageal narrowing when a balloon catheter can be passed safely through the stenotic area. Low-compliance balloon catheters are commonly used.[43] The effect of balloon dilatation varies with the type of pathology, and patients with membranous web of the esophagus and some cases of fibromuscular stenosis can be treated by suitable dilatation.[11,26,28,29]

It is thought that the efficacy of balloon dilatation in CES with tracheobronchial remnants is limited.[51] However, it is difficult to precisely assess the efficacy of balloon dilatation among the different types of CES pathology. This is because the histological findings of the stenotic lesions of the patients who respond positively to dilation remain unconfirmed. Currently, the responsiveness of patients with CES with tracheobronchial remnants to dilatation is uncertain. Recently, a case of successful treatment of membranous web

with the use of endoscopic instruments (electrocauterization, high-frequency-wave snare/cutter) was reported.[55,56]

Surgery

When patients fail to respond to repeated (four to six times) attempts of bougienage, surgical intervention should be considered. Surgical resection of the stenosis followed by end-to-end esophageal anastomosis is a general surgical treatment, typically used in cases with tracheobronchial remnants[6,8,10–16,37,40–43] and some cases with fibromuscular thickening.[21,34]

Most cases of CES can be operated upon using the thoracic approach. However, when the stenosis is located in the abdominal esophagus, laparotomy is utilized. In a few cases of CES, complete resections of the stenotic segment using the thoracoscopic[57,58] or laparoscopic approach[59] have been reported.

In the thoracic approach, right thoracotomy is employed for stenosis in the middle esophagus, and left thoracotomy is employed for stenosis in the lower part of the esophagus. After exposing the esophagus, a balloon catheter is inserted from the mouth to locate the stenotic segment. The catheter is then inflated and pulled up to confirm the lower margin of the stenosis. Following the cut in the distal end of the stenosis, a sterile balloon catheter is passed through the stenotic area from the oral stump of the esophagus. The upper margin of the stenosis is determined by pulling down the catheter (Figure 47.5).[43]

The stenotic area is completely removed, and end-to-end anastomosis is achieved using single- or double-layer interrupted sutures of absorbable material. Surgeons should ensure that the phrenic and vagal nerves are not damaged during the surgery.

Other options for surgical treatment include simple excision of cartilaginous remnants, longitudinal myotomy, circular myectomy, and esophageal replacement. Among these procedures, simple excision of the cartilaginous remnants and subsequent repair of the esophageal wall have been reported.[5,11,43] However, these methods are rarely employed because they fail to provide sufficient relief from symptoms in most cases of CES with tracheobronchial remnants.

Longitudinal myotomy, which is more often used for esophageal achalasia than for CES, has been employed for fibromuscular stenosis. However, postoperative dilatation is frequently required, and its efficacy remains unconfirmed. Moreover, development of esophageal perforation after myotomy has been reported.[42]

Circular myectomy for CES with tracheobronchial remnants has been described,[60,61] and it might be employed for fibromuscular stenosis as well. During this surgical procedure, the lower margin of the stenotic segment is delineated while pulling up a balloon catheter inserted through the mouth. This is similar to the technique followed during resection of the stenotic portion. The upper margin is determined by pushing down the balloon catheter inserted through the mouth or by pulling down the balloon catheter inserted through a small incision at the esophageal mucosa into the esophageal lumen. The muscular layer is incised up to the submucosal layer at the lower and upper margins. Subsequently, the abnormal muscular layer is dissected circumferentially using surgical scissors or cauterization. Circular myectomy is expected to prevent postoperative leakage and re-stenosis of the esophageal anastomosis.[60,61]

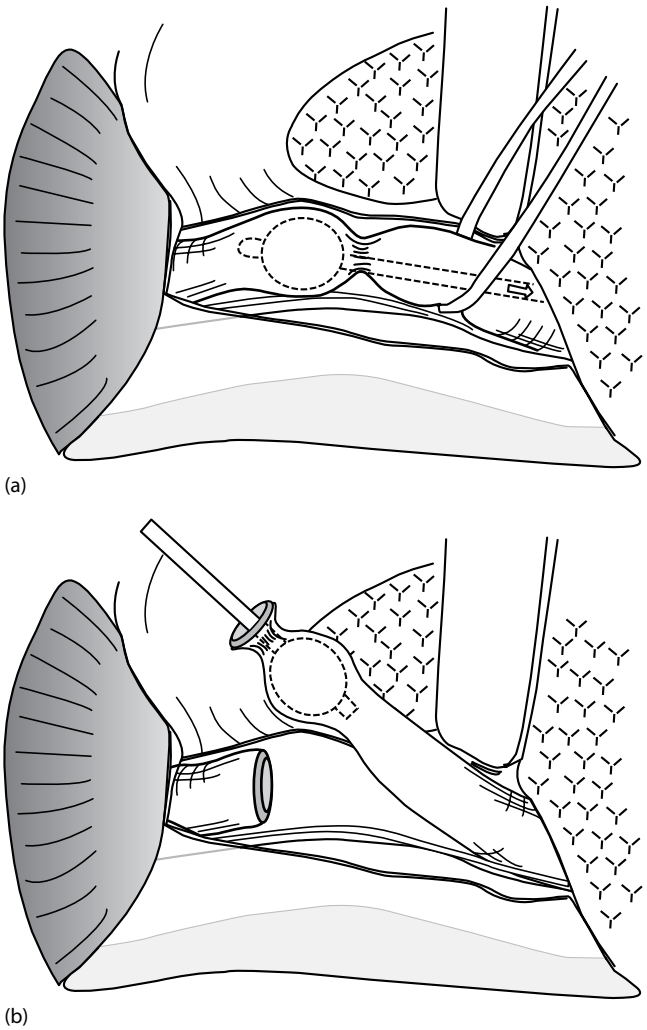

Figure 47.5 Intraoperative procedure by use of a Foley catheter to determine the distal **(a)** and proximal sites **(b)** of stenosis.

Among various methods of surgical treatment for CES, segmental resection with end-to-end anastomosis of the esophagus is currently the standard procedure, and circular myectomy is a promising alternative. Both procedures pose a substantial risk of developing GER, particularly when anastomosis is performed under tension. When the stenosis is situated close to the gastroesophageal junction and the surgery is performed through laparotomy, an antireflux procedure might be employed as well to prevent postoperative reflux.[43] If the vagal nerve is accidently severed, a pyloroplasty is performed.

Patients with extensive CES, necessitating the resection of >3 cm of the esophagus, might require esophageal replacement using the colon, jejunum, or a gastric tube.

MANAGEMENT OF COMPLICATIONS FOLLOWING TREATMENT

Complications, including iatrogenic esophageal perforation following bougienage[10,42,57] and leakage following segmental resection and reconstruction of the esophagus,[11] have been reported. The rate of esophageal perforation upon dilatation has been reported as 9.1%–44%.[41,43,46,51,62] Perforations and large leakages might require surgical drainage and/or repair, but minor leakages can be treated successfully by maintaining the patient on total parenteral nutrition. When GER develops following simple resection or circular myectomy, an antireflux procedure is required.

PROGNOSIS

Favorable results have been reported following appropriate treatment. Amae et al.[43] reported the treatment outcome of 14 patients with CES, of whom 11 and 3 patients became asymptomatic following surgery and dilatation, respectively. On the other hand, according to a recent report of 61 cases of CES by Michaud et al.,[63] dysphagia occurred frequently, regardless of therapeutic option, and it remained in 36% of the patients at the time of follow-up. Close, long-term follow-up is highly recommended.

Esophageal duplication cysts

DAKSHESH H. PARIKH AND MICHAEL SINGH

INTRODUCTION

Esophageal duplications and bronchogenic cysts are part of the spectrum of foregut malformations as both seem to have their origin from the primitive foregut.[1] Foregut duplication cysts in children account for up to one-third of mediastinal cysts and are one of the main differential diagnoses for posterior mediastinal tumors. In the literature, approximately 21% of gastrointestinal duplications are reported to be of esophageal origin.[2,3]

Esophageal duplication cysts are seen in close proximity to the native esophagus. There may be associated duplications elsewhere in the gastrointestinal tract. Some of the esophageal duplications can be thoracoabdominal in nature.[4,5] In contrast, bronchogenic cysts are more frequent and are closely associated with the tracheobronchial tree or within the lung parenchyma. Unlike bronchogenic cysts, esophageal duplication cysts are commonly associated with vertebral anomalies. In the presence of a vertebral anomaly, rarely, an intraspinal communication can be identified. This variant is called a neuroenteric cyst.[6]

ETIOLOGY

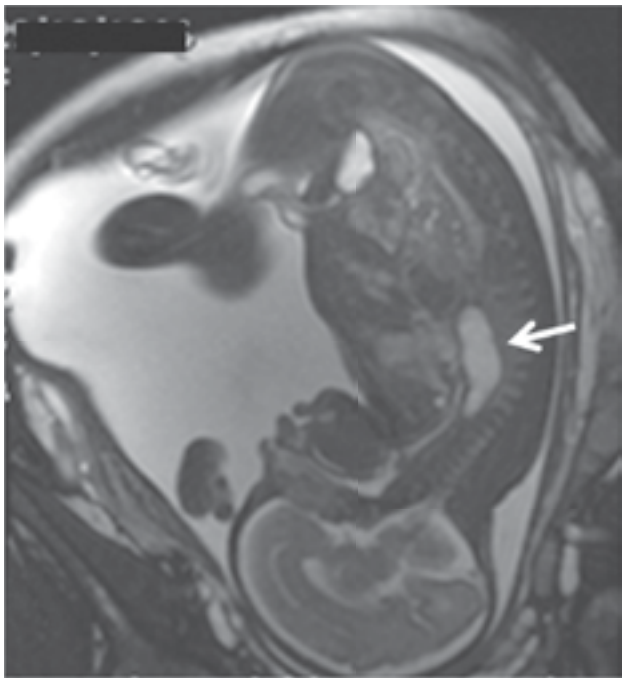
Esophageal duplications are thought to be a result of an aberrant dorsal foregut development during the fourth to eighth week of gestation. One of the embryological theories implicates inappropriate canalization or failure of connection of the vacuoles as canalization of the gastrointestinal tract occurs to form a lumen. The other theory proposes a diverticulum occurring during the development of the gastrointestinal tract that may result in duplication with or without connection with the intestinal lumen. Both these theories fail to explain the various types of duplications occurring in the gastrointestinal tract. The split notochord theory, in contrast, can explain the association of vertebral anomalies with mediastinal duplications. The notochord is formed by the ingrowth of the mesodermal cells and separates from the endoderm. In the event of adhesion with the endodermal lining, it is drawn inside the spinal canal, not allowing the spinal canal to close ventrally. It is possible that both ends of this connecting tract may remain open or closed on either side. The cephalic end may represent a fibrous cord, connect to the cysts on either side, or disappear altogether as seen in most instances.[1]

PATHOLOGY

Esophageal duplications are described as cystic, tubular, or neuroenteric in nature. Over 60% of esophageal duplication cysts are mainly associated with the lower esophageal, and the rest are identified within the upper and middle thirds of the esophagus. They generally have a thin wall of muscle coat and are in close proximity to the native esophagus or can be within the esophageal wall. Rarely, some of the esophageal duplications can be simple epithelial-lined cysts. The cysts can contain either a clear mucoid, brown, or blood-stained serous fluid. The majority do not communicate with the spinal canal or have an associated vertebral anomaly. Duplication cysts can have a wide variety of mucosal linings: squamous, gastric, pseudostratified, cuboidal, columnar, ciliated respiratory tract lining, or pancreatic cells.[4,5] A mixed epithelial lining within the cyst is commonly reported.[3,7,8] The symptomatic duplication may therefore bleed within the cyst or cause pressure symptoms onto the surrounding structures such as the trachea, esophagus, or result in formation of a fistula.

PRESENTATION

The majority of esophageal duplication cysts present in early childhood, of which some are antenatally detected (Figure 48.1a). In our experience of the antenatally detected cystic thoracic lesions, approximately 5% of cases are subsequently diagnosed as foregut duplications. The majority of antenatally detected cases are asymptomatic at birth.

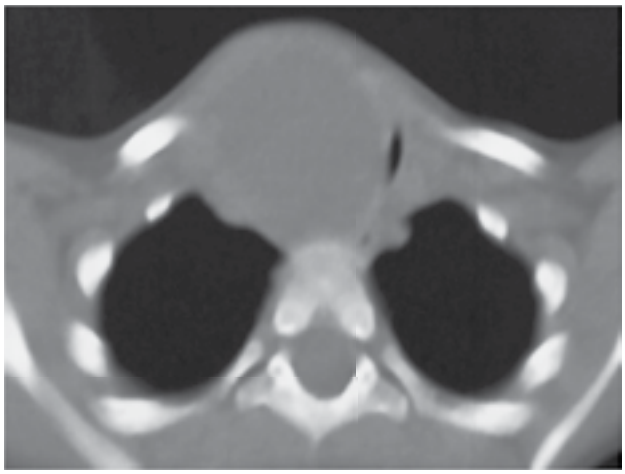


(a)

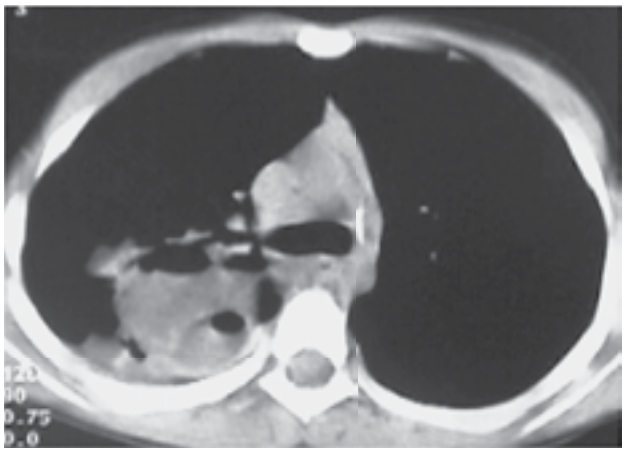
(b)

Figure 48.1 **(a)** Fetal MRI confirming antenatal ultrasound findings of foregut duplication cyst with intraspinal extension. **(b)** Postnatal MRI showing a large tubular esophageal duplication cyst (hollow arrow) with a cervical intraspinal component (white arrow).

Patients can present in infancy with acute respiratory distress, stridor, dysphagia, meningitis, and the sudden appearance of a cervical mass (Figure 48.2a,b). Sudden death has been reported in some untreated cases, where the most plausible explanation would be the rupture of the cyst into the tracheobronchial tree.[8,9]



(a)



(b)

Figure 48.2 **(a)** CT scan demonstrating a large cervical esophageal duplication with tracheal compression and deviation, in a patient with acute stridor and sudden appearance of a cervical mass. **(b)** CT scan showing an infected duplication cyst with a fistula into the right-upper-lobe bronchus. This patient had recurrent pneumonia and developed a right-upper-lobe lung abscess seen on chest x-ray.

Occasionally, duplications may be an incidental finding on chest x-ray (Figure 48.3). The symptoms in older children are generally related to pressure on the surrounding structures. Esophageal compression causes dysphagia (Figure 48.4b). Tracheal compression results in stridor or respiratory compromise (Figure 48.2a). These cysts may ulcerate, bleed, and rupture into the esophagus or tracheobronchial tree, causing recurrent pneumonia, pain, hemoptysis, and lung abscess (Figure 48.2b).[3,7,8] Both squamous cell carcinoma and adenocarcinoma in esophageal duplication cysts have been reported in adults.[10,11]

A high preoperative mortality (10%) has been reported in a large retrospective study.[8] The reported deaths are a consequence of exsanguinating bleeding into the esophagus, respiratory compromise, or septic complications.[8]

Figure 48.3 Incidental chest x-ray finding of a duplication cyst in a previously asymptomatic patient. This x-ray was done for blunt chest trauma. Subsequent investigation confirmed this to be an esophageal duplication.

DIAGNOSIS

All antenatally diagnosed thoracic cystic lesions must be investigated postnatally with a contrast-enhanced computed tomography (CT) scan. A foregut duplication on CT scan is located in the posterior mediastinum in contact with the esophagus or trachea. Typically, it is described as a low-attenuation, homogenous cystic mass with a smooth border (Figures 48.4c and 48.5d).[12]

Plain x-ray may reveal a paravertebral, smooth round shadow. In symptomatic cases, there may be a deviated or compressed trachea (Figures 48.2a and 48.4c). The plain radiograph is also useful in demonstrating associated vertebral anomalies (Figure 48.5a).

In children presenting with dysphagia, a contrast swallow will demonstrate a smooth shadow compressing the esophageal tract (Figure 48.4b). In the acute onset of stridor, a CT scan will show a cystic mass causing tracheal compression (Figure 48.2a). The lower esophageal duplication cysts are likely to remain asymptomatic and can present in adulthood either on an incidental x-ray or with symptoms such as chest pain, dysphagia, or hematemesis (Figure 48.5b). A magnetic resonance imaging (MRI) scan should be considered in the presence of vertebral anomalies for the diagnosis of an intraspinal component (Figures 48.1b and 48.5c). Upper gastrointestinal endoscopy and esophageal ultrasonography add little to the diagnosis of the esophageal cyst.

MANAGEMENT

Esophageal duplications warrant complete excision as incomplete excision inevitably results in a recurrence.[8] Antenatally diagnosed cases after investigations should be electively excised, preferably with the thoracoscopic approach. In most instances, symptomatic cases are suitable for thoracoscopic resection with the exception of infected cases with fistulation (Figure 48.2b). Thoracoscopic excision is being increasingly used for the surgical management of esophageal duplication cysts.[13–15] The thoracoscopic approach has been shown to have lower opioid requirements and shorter duration of chest tube drainage and hospital stay.[14,15] Previous inadequate resection with recurrence may require an open approach for a complete resection.

Thoracoscopic resection

Central endotracheal intubation is used in most cases, with the exception of older children, where single-lung anesthesia is possible. The patient is placed in the lateral position, with the affected side uppermost. The optical port is generally inserted just anterior to the angle of the scapula in the midaxillary line. Two or three additional ports are inserted under thoracoscopic vision for the best possible triangulation and manipulation. The lung is collapsed and retracted with creation of a pneumothorax with minimal pressures (5–7 mmHg of CO_2, flow rates of 1.5–2 L/min) to expose the posterior mediastinal cyst.

The pleura at the base of the cyst is incised with either scissors or diathermy hook. Two types of duplications are encountered requiring slightly different techniques during its resection. The commonly encountered duplication has a separate muscle wall and is attached to the native esophageal tract by connective tissue. The dissection can be completed using either diathermy hook or scissors, harmonic scalpel, or LigaSure (Valley Lab, Covidien). Electrosurgical instruments should be used precisely and with caution so as to prevent inadvertent tissue injury by electrical conduction or thermal spread. The vagus and phrenic nerves and thoracic duct are at risk of injury during the resection of the thoracic inlet duplication. Esophageal duplications sharing a common muscle wall with the native esophagus are relatively rare and a technical challenge to resect thoracoscopically. A nasogastric tube or an endoscope placed in situ during resection can help avoid resection of a major portion of the wall and mucosa of the native esophagus. The cyst should be completely excised with the esophageal mucosa left intact if possible. Marsupialization should be avoided as leaving residual cyst wall tends to result in recurrence.[8] Once the cyst is removed, the defect in the esophageal musculature and mucosa can be sutured with absorbable sutures. The specimen is decompressed by aspiration and delivered by expanding one of the anterior ports.

In the presence of a thoracoabdominal duplication cyst, complete resection is achieved by an additional laparoscopic

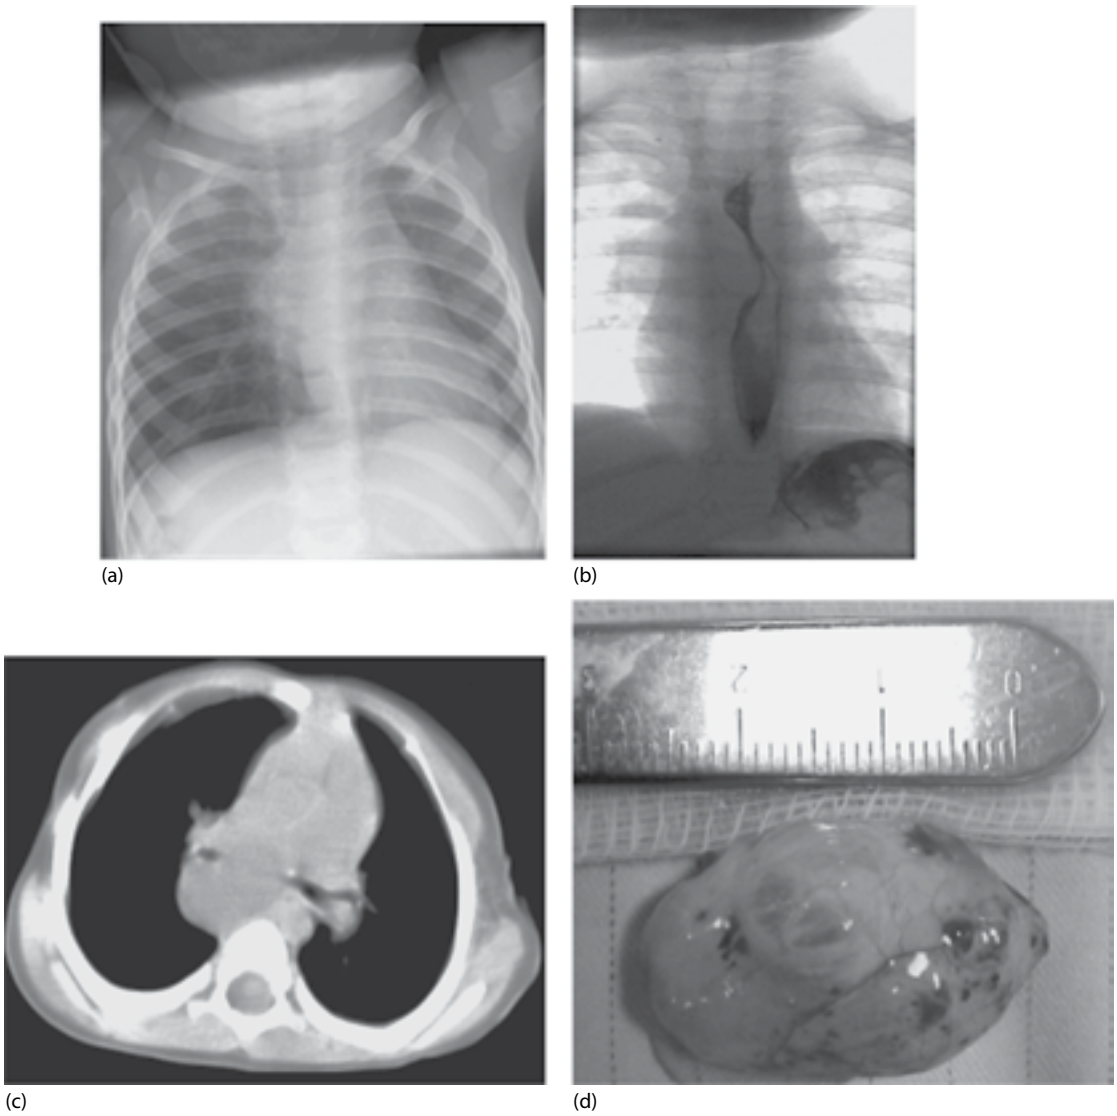


Figure 48.4 **(a)** This patient presented with recurrent chest infections. Chest x-ray shows mild emphysema of the right lung with a smooth round mediastinal mass. **(b)** A contrast swallow shows the classical smooth shadow compressing the esophageal tract. **(c)** CT scan revealed a typical low-attenuation, homogenous cystic mass with a smooth border compressing the right main bronchus. **(d)** Duplication cyst specimen following thoracoscopic excision.

approach. A separate intra-abdominal cyst can be successfully resected either in the same sitting or at a subsequent laparoscopic resection.[5]

Most esophageal duplications following resection do not require postoperative chest drains. We recommend a chest drain only if the esophageal mucosa is breached during the resection.[16] Postoperative pain is managed with oral or intravenous paracetamol and oral anti-inflammatory drugs (ibuprofen). The majority of thoracoscopically resected cases can be discharged the following day.

Thoracotomy and resection

A lateral thoracotomy through the bed of the fifth rib is recommended for an open resection. The principles of surgery are the same as for thoracoscopic resection. Adhesions, either inflammatory or as a result of a previous operation, are the cause of complications in open operations. Bleeding and air leaks either from the lung parenchyma or from fistulation should be managed intraoperatively in order to avoid postoperative complications. The aforementioned nerves and thoracic duct are also at risk of injury as bleeding or adhesions may obscure their presence near the duplication.

Cervical and suprasternal cysts

Cervical excision can be achieved by placing the patient supine with a roll under the shoulders. Once the cyst wall is identified, the dissection is continued staying close to its surface. Electrosurgical instruments should be used precisely and with caution so as to prevent inadvertent tissue injury by electrical conduction or thermal spread. The

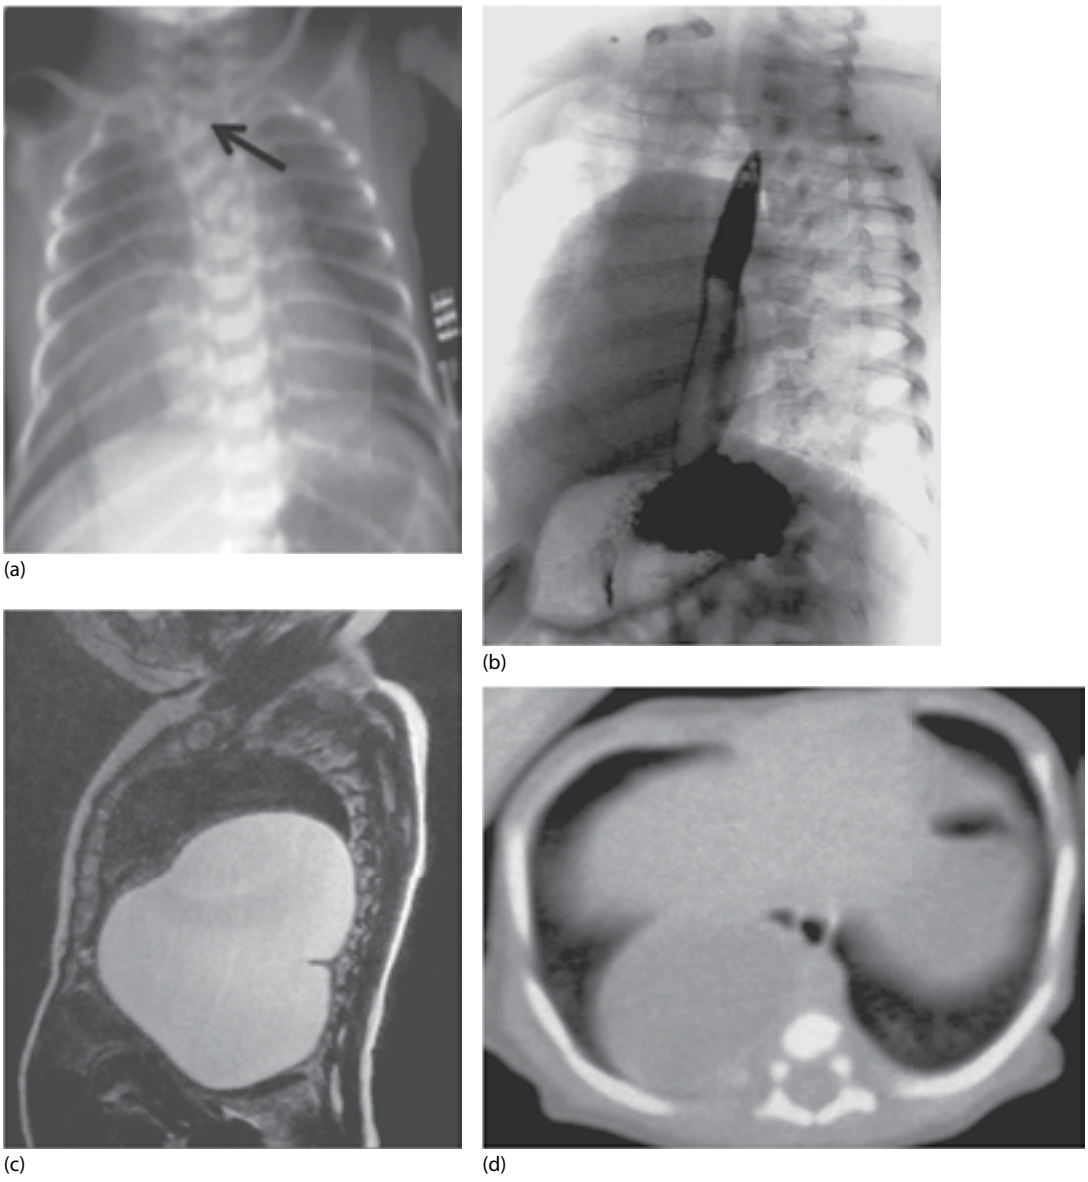

Figure 48.5 **(a)** Chest x-ray showing vertebral anomalies in an antenatally detected foregut duplication cyst. **(b)** Contrast study demonstrating a large posterior mediastinal duplication cyst. **(c)** MRI scan was done to rule out neuroenteric component in presence of vertebral anomalies. **(d)** CT scan confirmed a smooth low-attenuation posterior mediastinal duplication cyst.

recurrent laryngeal nerve is particularly at risk of injury as it can travel on the surface of the esophageal duplication.

SURGICAL COMPLICATIONS

Surgical complications are related to the site and mode of surgery. Incomplete excision is associated with recurrence and the need for further surgery.[8] Esophageal leakage is a possibility with both the open and the thoracoscopic approach. A minor leak can be managed conservatively with a period of nil by mouth with parenteral nutrition, antibiotics, and chest drainage. However, major leaks may require thoracotomy, esophageal repair, evacuation of the empyema, and chest drainage.[7,13] This group of patients is at risk of esophageal stricture long term, which may respond to dilation. Esophageal pseudodiverticulum is a long-term risk if the esophageal musculature is not approximated.[15] A persistent air leak will require thoracotomy and formal repair of the bronchus or trachea.[13] In a retrospective series, two postoperative deaths have been reported secondary to septic complications, one from an esophageal leakage and the other from cyst-related sepsis.[8]

Injury to the vagus nerve, recurrent laryngeal nerve, and phrenic nerve in the cervical and the superior mediastinial duplication can be avoided by careful dissection and staying close to the cyst wall. Judicious use of electrosurgical instruments in dissecting close to the nerves is recommended. There is a higher risk of nerve or thoracic duct

injury during surgery for an infected cyst because of adhesions and bleeding.

LONG-TERM OUTCOME

All esophageal duplications should be excised because of the potential for life-threatening complications: peptic ulceration and bleeding or perforation, acute airway obstruction, recurrent infection, mediastinitis, meningitis, and the long-term risk of cancer. Thoracoscopic excision in the asymptomatic patient has a lower complication rate than surgery for a cyst-related complication. Patients who are known to have incomplete excision should be monitored for recurrence. Patients with vertebral anomalies should be monitored for scoliosis. Rarely, a motility disorder of the esophagus is noted in some cases after resection as a result of damage to the pharyngeal plexus. After resection of the cervical duplication, a pharyngeal pouch can be a long-term consequence.

Esophageal perforation in the newborn

DAVID S. FOLEY

INTRODUCTION

Iatrogenic esophageal perforation occurs rarely in neonates and was first reported in the literature by Eklof and colleagues.[1] In the past two decades, perforation of the esophagus in extremely premature neonates has become increasingly recognized and reported. Spontaneous perforation of the esophagus (neonatal Boerhaave's syndrome) is extremely rare, and Fryfogle[2] performed the first successful repair. Despite the favorable results of nonoperative management in cases of neonatal esophageal perforation, this condition may be fatal without early diagnosis and treatment, and aggressive surgical therapy is occasionally warranted.[3–7] Surgeons must continue to play a central role in the individualization of care in these patients.

CLASSIFICATION AND ETIOLOGY

Esophageal perforation in newborns can be classified as iatrogenic or noniatrogenic. Noniatrogenic perforations are extremely rare and are usually seen in full-term infants when they occur. The most common site of perforation is the lower third of the esophagus. Etiological hypotheses for spontaneous perforation include increased intra-abdominal pressure at delivery, perinatal hypoxemia, and reflux-associated peptic esophagitis.[8]

Iatrogenic perforation of the esophagus is most commonly seen in premature, small-for-gestational-age (SGA) infants,[9] and usually occurs in the cervical esophagus or hypopharynx. Pharyngeal suctioning with a stiff catheter, traumatic laryngoscopy, esophageal intubation, and digital manipulation of the neonatal head during breech delivery have all been described as causative.[10–13]

During instrumentation, when the neck is hyperextended, perforation of the esophagus may occur at the level of the cricopharyngeus muscle, where the posterior esophageal wall is compressed by the sixth or seventh cervical vertebra. Submucosal injury by a laryngoscope blade or endotracheal tube may be the initial injury to the hypopharynx, resulting in cricopharyngeal spasm.[14] Endotracheal intubation, especially in premature, SGA neonates, may further compromise the esophageal introitus. Subsequent oropharyngeal suctioning or insertion of a nasogastric tube may extend the submucosal injury into a full-thickness perforation.

Perforation of the middle esophagus is usually associated with dilatation of a stricture, or a postoperative anastomotic leak following esophageal atresia repair.[15,16] An improperly placed chest tube may cause disruption of a fresh esophageal anastomosis or may penetrate a proximal myotomy site.[17] Chest tube–related direct pressure necrosis of an otherwise normal esophagus has been reported in a premature neonate.[18] With the increasing use of transesophageal echocardiography in the evaluation of congenital heart disease, perforations of the proximal and middle esophagus have been reported with this procedure.[19,20]

Distal esophageal perforation may be associated with dilatation of an esophageal stricture secondary to esophagitis, a technical error during antireflux surgery, or a misplaced gastrostomy balloon.[21]

DIAGNOSIS AND CLINICAL MANIFESTATIONS

Newborns with iatrogenic esophageal injury may demonstrate excessive salivation and mucoid secretions due to difficulty swallowing, and many will have overt respiratory distress. The examiner will have difficulty passing a nasogastric tube, either as the inciting event or as a result of swelling or a false tract created by prior instrumentation. In neonates, an abnormal position of the nasogastric tube on postplacement chest x-ray is commonly the first indication of esophageal perforation.[9]

In premature infants, the presence of blood-tinged oral secretions after endotracheal intubation warrants serial x-ray examinations of the chest. The proper diagnosis often will be missed in the absence of such an examination. The symptoms of perforation may not be recognized until the child develops esophageal obstruction, and may be mistaken for esophageal atresia.[9,11,13] Esophageal perforation may be differentiated from

atresia of the esophagus by an asymptomatic interval after birth, a premorbid history of repeated attempts at intubation or vigorous suctioning, absence of prenatal polyhydramnios, and the position and course of the nasogastric tube on chest x-ray.[9] Some perforations of the esophagus create respiratory distress secondary to the development of hydropneumothorax. In these cases, the right pleural space is most commonly affected.[3,5,11,13] Thoracentesis or tube thoracostomy should yield serosanguinous fluid or the contents of the previous feeding. Chylopneumothorax has also been reported in association with neonatal esophageal perforation.[22]

Anteroposterior and lateral x-rays of the chest and neck should be obtained in any suspected case of perforation. The abnormalities seen in these cases depend on the site of injury. Hypopharyngeal and cervical perforations frequently demonstrate extraluminal air in the neck, without pneumomediastinum initially. Midesophageal perforations may demonstrate pneumomediastinum, pneumothorax, or hydrothorax. An unusual course of the nasogastric tube (right pleural cavity, pericardial cavity [Figure 49.1], or right side of the mediastinum) supports the diagnosis and may be confirmatory. Widening of the mediastinum and blurring of the mediastinal margin may occur secondary to the development of mediastinitis, but are later and more subtle findings. These changes should prompt esophagography. Mollit et al.[23] described three types of injuries that are seen in premature neonates: (1) a pharyngeal diverticulum created by a local cervical leak; (2) a mucosal perforation extending posteriorly in parallel to the esophagus; and (3) a free intrapleural perforation where there is obvious leakage of air and esophageal contents into the pleural cavity.

In cases where chest x-ray demonstrates the nasogastric tube to be located in the pleural cavity or pericardium, the diagnosis of esophageal perforation can be confirmed (Figure 49.2). In this situation, precise localization of the site of perforation may be unnecessary, unless the patient's clinical condition deteriorates after removal of the nasogastric tube and tube thoracostomy drainage. If symptoms suggest esophageal obstruction, esophagography should be performed by administering a small quantity of diatrizoate meglumine (Hypaque), diatrizoate sodium (Renografin) or metrizamide into the proximal esophagus; Gastografin and barium should be avoided due to the risk of worsening mediastinitis or inducing significant pulmonary inflammation with aspiration. In cases of pharyngeal–esophageal perforation, cricopharyngeal spasm may be so severe that no contrast material will enter the native esophagus. In these cases, several clues may help to differentiate submucosal perforation or pseudodiverticular formation from congenital esophageal atresia.[24] These include the following:

- The distance between the trachea and opacified tract on lateral x-ray is greater than that of the pouch in a congenital esophageal atresia, which is closely associated with the trachea.
- The opacified tract in perforation cases is longer, narrower, and more irregular than in esophageal atresia.
- The trachea is slightly compressed on lateral x-ray by the upper pouch in esophageal atresia, but this is not so in esophageal perforation.

Esophagoscopy is usually not indicated at the time of diagnosis and may actually enlarge the perforation.

Spontaneous perforation of the neonatal esophagus usually presents with respiratory distress, which may be immediate or delayed for several hours after the event. There is a greater predilection for right-sided pneumothorax in neonatal Boerhaave's syndrome, in contrast to the left-sided

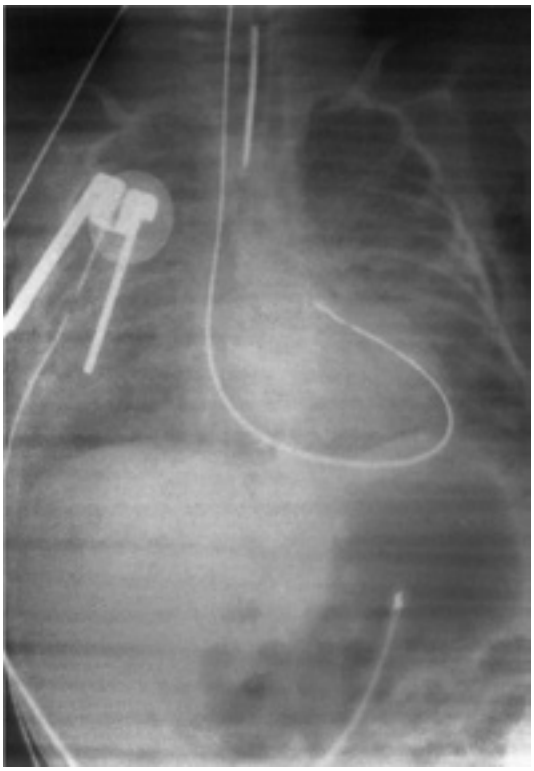

Figure 49.1 Chest x-ray shows displacement of the nasogastric tube to the pericardial sac.

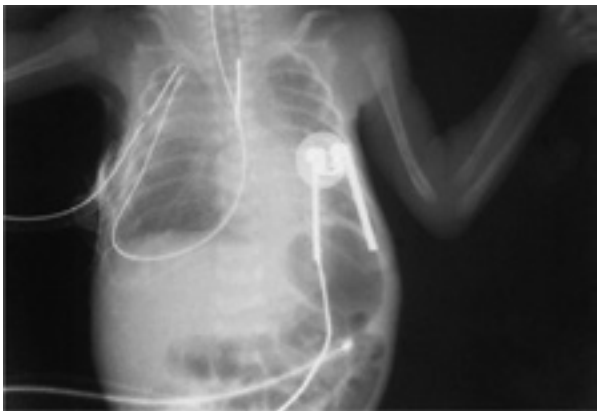

Figure 49.2 Anteroposterior view demonstrates coiled nasogastric tube in right pleural cavity and chest tube placed for tension pneumothorax.

pneumothorax typically seen in adults.[8,18] This may be explained by the close adherence of the aorta to the left side of the esophagus in neonates, which provides an additional mediastinal barrier on the left side. If the perforation remains undiagnosed, respiratory distress will worsen with subsequent feedings. Esophagography must be performed in all suspected cases of free perforation to evaluate the extent of the damage and to localize it.

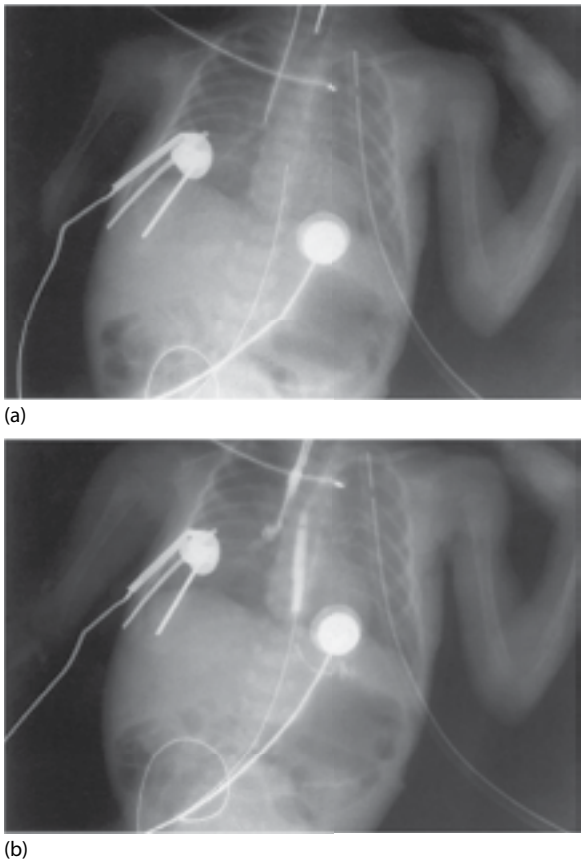
MANAGEMENT

The management of neonatal esophageal perforations has favored a selective approach in recent years.[7,23–25] Esophageal perforation can be a rapidly fatal condition that requires immediate recognition and aggressive management for a successful outcome. However, the treatment of esophageal perforation must be individualized according to the site and size of injury, the systemic response of the neonate, and the time interval between the injury and initiation of treatment. Small submucosal perforations of the hypopharynx and esophagus, limited to the mediastinum and without systemic symptoms, may be managed by nonoperative methods (Figure 49.3). Identification of the exact site of perforation is not essential in these infants. If the nasogastric tube is noted in the mediastinum or pericardial cavity, the tube can be withdrawn and a new tube placed under fluoroscopic control. A broad-spectrum antibiotic must be given for 7–14 days. Intravenous (IV) fluids and hyperalimentation should be administered, as oral feedings must be withheld. Esophagography should be performed 7–10 days after the injury. If the perforation is completely healed, oral feeding may be resumed. If the perforation has not healed during this interval, conservative treatment for another week will usually allow complete healing.

In general, routine surgical intervention does not appear to improve the rate of survival in these newborns. Tube thoracostomy should be placed when the chest x-ray indicates pneumomediastimun, pneumothorax, or hydrothorax (Figure 49.4). All newborn infants with esophageal perforation must be carefully monitored during treatment, including the use of white blood cell counts or C-reactive protein levels, platelet counts, blood gas analyses, and chest x-ray evaluation. If there is clinical deterioration or respiratory compromise, and closed-chest drainage does not handle the leak, direct repair of the perforation is indicated.

In cases where direct repair of the perforation is not technically feasible because of scarring, inflammation, and tissue friability, diverting cervical esophagostomy with closure of the perforated area and concomitant gastrostomy is indicated. If at all possible, efforts should be made to avoid future esophageal replacement. Long, linear perforations to the lower end of the esophagus require an immediate thoracotomy, debridement of the necrotic edges, and primary repair of the defect with pleural flap coverage. A gastrostomy tube may be inserted in these situations to minimize the risk of gastroesophageal reflux during healing.

If there is a delay of more than 24 hours in the diagnosis of a spontaneous perforation of the esophagus, unprotected primary repair cannot be safely accomplished. After adequate debridement, the treatment should be local esophagectomy with closure of the proximal and distal esophagus, proximal esophagostomy, and gastrostomy tube placement. Critically ill newborns should be managed with chest tube drainage, cervical esophagostomy (with or without ligation



(a)

(b)

Figure 49.3 Aberrant position of nasopharyngeal tube within mediastinum **(a)**, with confirmation of contained proximal esophageal perforation on subsequent contrast evaluation **(b)**.

of the cardioesophageal junction), and gastrostomy.[26] Broad-spectrum antibiotics, IV fluids, and hyperalimentation should be continued until clinical signs of sepsis improve. Gastrostomy feedings may be attempted after 48 hours. In cases where extensive debridement or resection is necessary, esophageal substitution is indicated after an interval of at least 6 months, when the mediastinal inflammation has resolved.

Perforations that occur following dilation of esophageal anastomotic strictures are usually managed nonoperatively, as long as the leak is contained or can be adequately drained by tube thoracostomy. These perforations may take some time to heal due to obstruction at the stricture site. In the last decade, endoscopic stenting has been reported as a means of containing leakage and promoting healing in these cases, although its use is limited in the neonatal population due to the size constraints of available stents.[27]

CONCLUSION

Iatrogenic perforation of the esophagus is more common than reported in the literature and may be fatal without early diagnosis. The incidence of recognized pharyngeal and esophageal perforations is low, however, considering the large number of pharyngeal instrumentations that are performed on premature infants in modern neonatal intensive care units.[23] Gentle laryngoscopy with proper visualization of the vocal cords during intubation, avoidance of protruding stylets, careful suctioning of the pharynx, and avoidance of forceful nasogastric tube placement are all essential factors in the prevention of these injuries.

It is generally accepted that most iatrogenic perforations of the esophagus in newborns are cervical and are made when inexperienced personnel attempt to intubate the trachea. With early diagnosis, most of these perforations can be managed nonoperatively with successful outcomes.[28] However, these infants should be monitored closely. If they develop systemic illness, appropriate operative intervention is often required. Early diagnosis of this condition allows for more treatment options, which include nonoperative therapy, closed-chest drainage, and primary repair. The mortality rate in neonates with esophageal perforation (4%) is significantly less than that in older children and adults (25%–50%).[6,7,29] Delayed diagnosis may result in the inability to repair the injury primarily, a significant increase in mortality, and the eventual need for esophageal replacement among survivors. Surgical consultation is warranted in all cases of esophageal perforation to allow timely and selective management, thereby limiting both mortality and long-term morbidity.

Gastroesophageal reflux in the neonate and small infant

MICHAEL E. HÖLLWARTH

INTRODUCTION

Gastroesophageal reflux (GER) is a term that describes the backflow of gastric content into the esophagus, sometimes reaching even the mouth. It is a common phenomenon and occurs in otherwise normal individuals several times during the day and night, especially after ingestion of fluids, e.g., soup, tea, coffee, or milk. Therefore, reflux episodes are more common in neonates and infants as long as they are nourished mainly with milk. The typical reflux symptoms in this age group are regurgitation, spitting up, and flaccid leak-out of milk after meals and when asleep. Pathological reflux defines a situation where the reflux causes symptoms in the neonate such as failure to thrive, sleep disturbance, and obviously, pain. The aim of this chapter is to discuss the normal esophagus in newborns and its function, the typical symptoms of reflux in this age group, investigating procedures, and conservative and operative therapy.

ANATOMY

The esophagus is a muscular tubular organ responsible for the transport of food from the mouth to the stomach. The upper half is composed of striated muscles, and its lower half consists of smooth muscle. The lumen is covered by a nonkeratinized, stratified squamous epithelium. At the esophageal–gastric junction, the epithelial layer changes to a monolayer columnar epithelium, the so-called cardia epithelium.

The diaphragmatic hiatus of the esophagus is fixed by the phrenicoesophageal membrane, which is incompetent in the case of a hiatal hernia (HH). The medial wall of the esophagus directly continues into the lesser curvature of the stomach, while the lateral wall forms a kind of incisure—the so-called His angle. Within the lumen at the His angle is a mucosal fold (flutter valve), which is passively pressed against the lower esophageal sphincter (LES) when the gastric fundus is filled, thus preventing reflux (Figure 50.1).[1] The flatter the angle of His, the less developed the flutter valve, and the more readily a reflux occurs for anatomical reasons.

INNERVATION

The esophagus has a parasympathetic innervation through the vagus nerve, which runs along the esophagus. Sympathetic innervation arises from postganglionic neurons of the sympathetic chain. The myenteric plexus and the submucosal plexus contain also nonadrenergic and noncholinergic nerves, and execute the complex activity of the esophagus through a number of neurotransmitters. Most important is a central regulation by consecutively activated nuclei in the brain stem responsible for the peristalsis and relaxations of the esophageal sphincters.

THE SPHINCTERS

There are two sphincter systems at the upper and lower end of the esophagus. In adult persons, the tone is in the upper esophageal sphincter (UES), markedly higher (between 40–80 mm Hg) than in the LES (15–25 mm Hg). The UES relaxes during propulsion of food from the oral cavity but also when refluxed volume reaches the upper esophagus from below. Then refluxed material can reach the hypopharynx and eventually the oral cavity.

Reflux of the contents of the stomach into the esophagus is prevented by the LES. The pressure ranges between 15 and 25 mm Hg in adults. On manometry, the pressure zone permits easy identification of the exact position of the sphincter. The pressure transition of the LES lies exactly within the diaphragm. The upper half of the sphincter can be assigned to the chest cavity, while the lower portion of the pressure zone is assigned to the abdominal cavity (Figure 50.2).

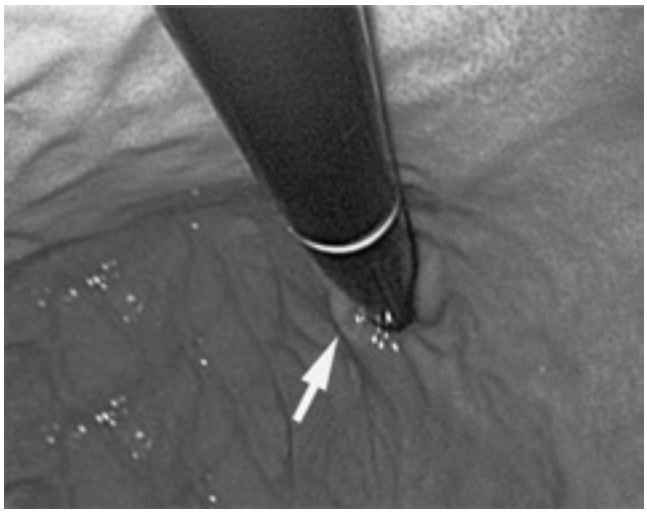

Figure 50.1 Typical mucosal flutter valve at the site of the His angle within the stomach.

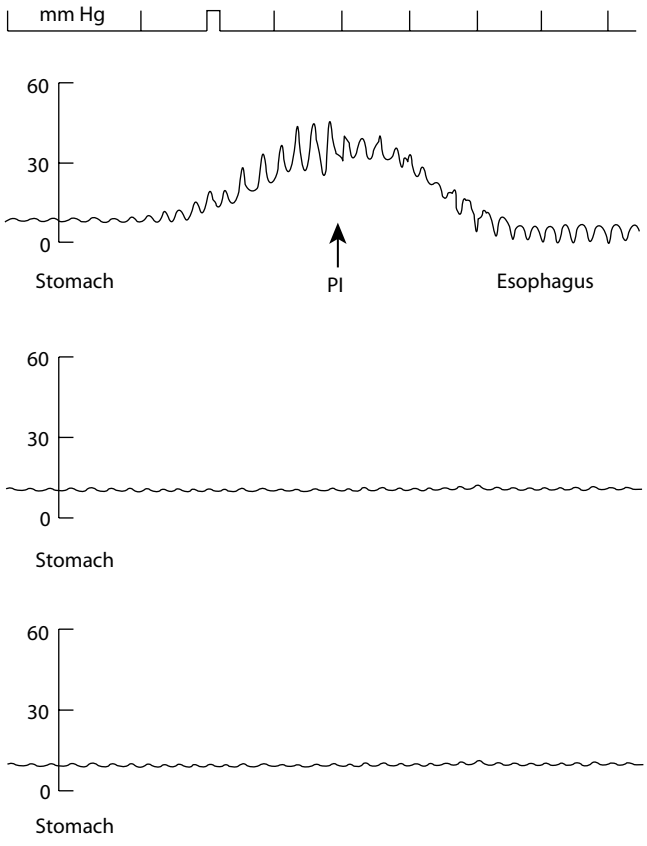

Figure 50.2 Slow pull-through manometry through the LES in a newborn child. PI indicates the pressure inversion from a typical stomach tracing to a typical esophageal tracing. Thus, the PI is located within the diaphragmatic hiatus, and one part of the LES belongs to the abdomen and the other part to the thorax. Except the sphincter, there is no intra-abdominal esophagus.

PERISTALSIS

Once food enters the esophagus, it is transported by a propulsive peristaltic wave into the stomach (primary peristalsis). With any local distension of the esophagus, as in cases of reflux, a propulsive peristaltic wave arises locally and transports the contents of the esophagus back into the stomach (secondary peristalsis). Isolated and disorderly contractions are defined as tertiary peristalsis or pathological contractions.

CAUSES OF REFLUX

One of the specific characteristics of the LES is the fact that its tonus does not only relax when food enters the esophagus through a propulsive peristaltic wave, but regular spontaneous relaxations of 5–10 seconds' duration (spontaneous transient LES relaxations [STLESRs]) occur even in the absence of any other esophageal activity in healthy individuals. Thereby, a common space is opened between the stomach and the esophagus and can be demonstrated on manometry as a sudden change of the typical esophageal tracing into an abdominal pressure curve, the *common cavity phenomenon* (CCP) (Figure 50.3). Usually, these relaxations remain unrecognized because the reflux reaches, in most events, only the lower esophagus. The volume is immediately returned to the stomach by a secondary peristalsis (volume clearance). Any drop in the pH, however, is neutralized in a stepwise manner by saliva during subsequent acts of deglutition (acid clearance). In patients with pathological reflux or reflux disease, STLESRs occur significantly more often and longer.

THE DEVELOPMENT OF THE ESOPHAGUS IN THE NEONATE AND SMALL INFANT

The best way to investigate the esophageal function in this age group is manometry combined with pH monitoring. Studies in premature infants and newborn babies have shown that the length of the LES is 10.7 mm. The tone of the LES is in these groups of babies was in the range of 18.0–23.0 mm Hg. Thus, the tone in the LES is identical with the tone in older age groups and in adults (Table 50.1).[2]

Manometric studies have shown that there is a physiologic delay in the development of propulsive esophageal peristalsis. Induced swallows in the youngest group of patients have been followed only in 59% by a propulsive peristalsis and in 41% by simultaneous contractions of the esophagus. However, already at the age of 4 weeks, nearly all investigated babies had a normal peristaltic response in 8 out of 10 induced swallows.

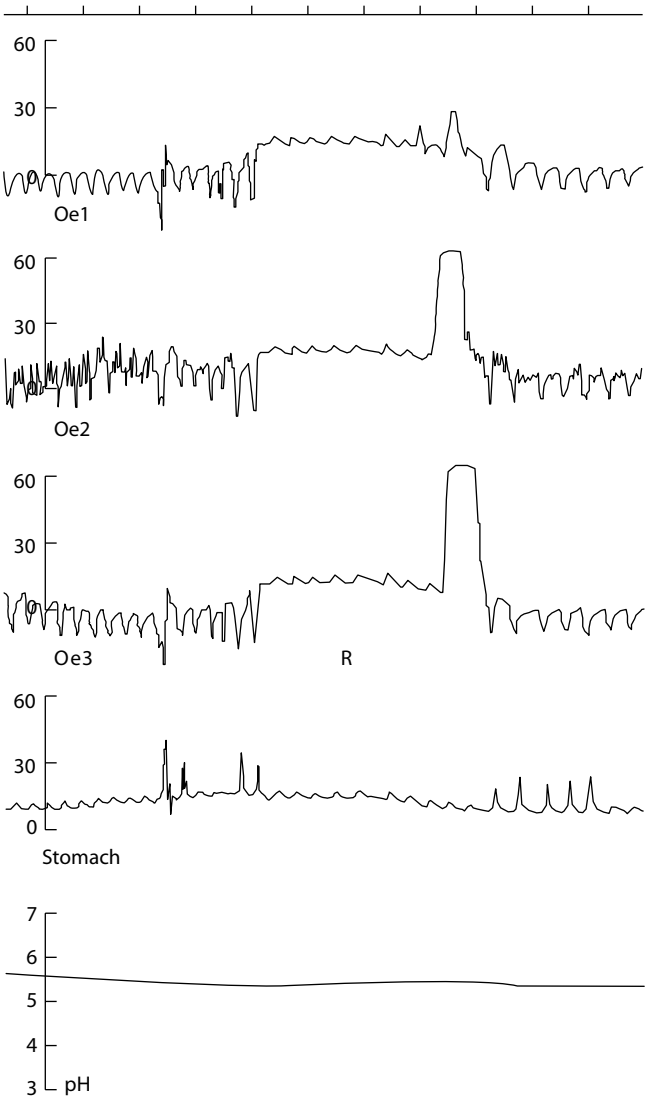

Figure 50.3 Spontaneous pressure inversion of the esophageal tracing to an abdominal tracing indicates the opening of the LES due to a transient relaxation. This is the manometric sign of reflux—the *common cavity phenomenon* (CCP). It is always terminated by a secondary propulsive peristalsis.

REFLUX IN THE NEWBORN

Mild spitting, a flaccid leak-out, or vomiting of milk as a sign of a pronounced GER is observed in approximately half of all newborns and young infants. The subsequent development shows that these symptoms become less frequent after the first 4–6 months of the infant's life and are no longer observed at 12 months in most cases. Previously, it was believed that frequent reflux in these early age groups is caused by a physiologic absence of tone in the LES. However, our former studies using adequate manometric techniques have clearly shown that the incidence of GER in newborns and infants is not caused by a low or even absent pressure of an immature LES, and not by a deficient esophageal peristalsis, but as a consequence of other factors (Table 50.1).

What is immature in this age group, and what might cause the higher incidence of reflux? Three factors have to be considered:

1. *Spontaneous LES relaxation:* We were able to show that GER in newborns and infants is caused by STLESRs. Babies with pathological reflux have significantly more frequent and more prolonged STLESRs but a normal LES tone (Table 50.2).[2,3] These findings were later confirmed by Omari et al.[4] Further investigations showed that pathological STLERs are associated with immaturity of the normal propulsive peristalsis of the esophagus. Thus, we can conclude that reflux in this age group is not caused by an absent LES tone but must be regarded as delay in the central motor coordination in the esophagus and its sphincters. The particularly high prevalence of reflux in infants with sleep apnea is an additional indication of the conclusion that immature central regulatory structures are responsible for frequent STLESRs.[5] In most cases, a spontaneous maturation of this functional instability occurs within the first year of life, and thereafter, the reflux pattern is identical with that of adults. However, it has been shown that the disappearance of the clinical signs of reflux around the age of 12 month does not necessarily mean that the

Table 50.1 Results of esophageal manometry

	n	Age (days)	LES tone (mm Hg) $\bar{x}$ ± SD	LES length (mm) $\bar{x}$ ± SD	PS *n* = 10
Premature infants (Gestational age [GA] 30–36)	7	7–28	23.0 ± 3.6	1.0 ± 1.1	–
Newborns	24	1–10	20.4 ± 8.0	10.7 ± 0.8	5.2*
Newborns	19	11–28	21.8 ± 10.0	11.0 ± 0.5	7.3
Infants	20	>28	18.0 ± 7.0	11.3 ± 1.1	7.9

Note: The LES pressure values in newborn babies and infants are already normal. *PS* is the response of propulsive peristaltic waves in the esophagus after 10 induced swallows. The results show that the response is significantly lower within the first 10 days of life, but thereafter, it is normal, with nearly 8 propulsive responses out of 10 induced swallows.

*$p < .05$.

Table 50.2 CCP occurs significantly more often and longer in babies with GER when compared to normal controls (However, the LES tone is not different between groups)

	Seconds	With reflux (*n*)	Controls (*n*)
CCP episodes	<7	12.4 ± 92.6[a]	3.3 ± 90.5
	7–15	9.6 ± 91.1[a]	3.4 ± 90.4
	>15	3.0 ± 90.8[a]	0.7 ± 90.2
Total CCP time (%)		2.0 ± 90.3[a]	0.5 ± 90.05
LES tone (mm Hg)		25.3 ± 92.6	30.2 ± 91.4

Note: CCP, common cavity phenomenon; GER, gastroesophageal reflux; LES, lower esophageal sphincter.

[a] $p < 0.05$.

esophageal function is normalized.[6] Despite persistent reflux, the clinical sign may be mild or even absent, but years later, sequelae of a chronic pathological reflux may become evident. Recent investigations in adults have shown that approximately half of young adults with reflux disease had marked symptoms in their childhood.[7]

2. *The His angle* is an other factor that may have a significant impact on the function of the LES and the incidence of spontaneous relaxations in this age group. In contrast to older children, the His angle in newborns and infants is not sharp but flat, and no mucosal valve can be seen during endoscopy (Figure 50.4). Any increased intragastric pressure after meals is then exerted directly toward the sphincter due to the lack of the mucosal valve mechanism.
3. Finally, it is well known that any *ingested fluid causes reflux* episodes. The largely liquid nutrition (milk) given in infancy is another factor causing frequent refluxes. The number of reflux events is significantly reduced toward the end of the first year as soon as nutrition is in larger quantities and more solid.

SYMPTOMS OF PATHOLOGICAL REFLUX IN NEWBORNS AND INFANTS

Pathological reflux in this age group may be characterized by different symptoms. The most typical reported signs are regurgitation and effortless leak-out of milk or food after meals, between meals, and when asleep. A moist pillow is another sign of reflux. Further symptoms of pathological reflux are restless sleep with sudden wake-up and crying periods. If recurrent vomiting of food is significant, the child may develop malnutrition and failure to thrive.[8–10] Rarely, one may even observe rickets despite seemingly adequate vitamin D supplementation as a consequence of the recurrent vomiting. Further suspicious symptoms are developmental disorders, recurrent respiratory tract infections due to microaspirations, greater irritability, and agitation. Quite often, reflux-related problems in feeding the baby may significantly disturb the interaction between mother and child. However, the clinical symptoms are not reliable indicators of gastroesophageal reflux disease (GERD), and show often a poor correlation with the results of 24-hour pH monitoring or histology.[11]

The most significant complication of GERD is esophagitis, which is caused by too frequent and prolonged relaxations of the LES and chronic acid exposure of the esophagus. The resulting inflammation of the mucosa may cause microbleeding and result in chronic anemia. If the inflammation spreads to deeper layers of the esophageal wall, it may eventually cause stenosis due to simultaneous formation of scars. However, in newborns and infants, as long as the babies are largely fed with milk, the acidic gastric juice is largely buffered during the first 2 hours after feeding (Figure 50.5). Thus, esophagitis is a very rare occurrence in this age group.

DIAGNOSIS OF REFLUX

There are several diagnostic tests to determine pathological reflux. However, in most cases, only a few of them are needed in the newborn age group. It depends on the underlying problem whether or not an extensive diagnosis is needed. In this section, the principal diagnostic tests to determine pathological gastroesophageal reflux will be described.

Radiological investigation of esophageal passage

The primary purpose of barium contrast radiography is to investigate the morphology and peristaltic function of the esophagus. Visualization of the gastroesophageal junction,

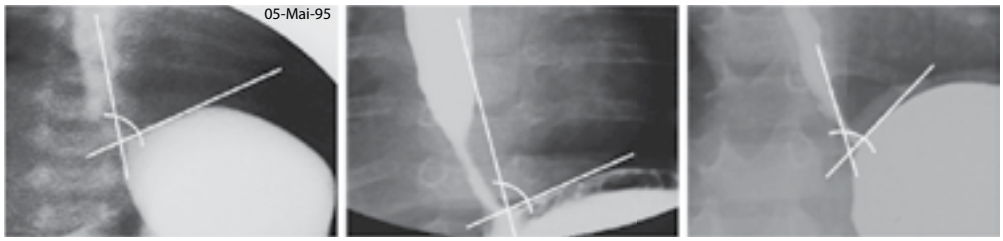

Figure 50.4 Development of the His angle: the diaphragm moves upward with age, and the His angle becomes markedly sharp-angled in this child with a primary GER problem.

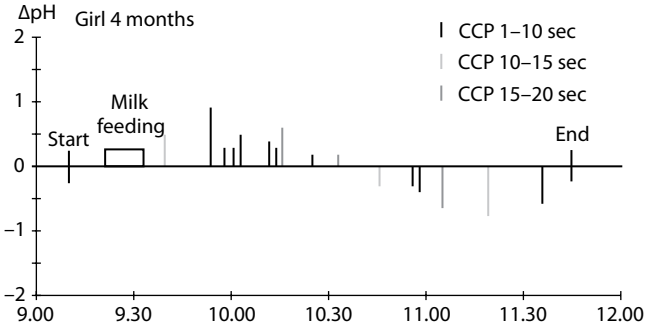

Figure 50.5 Combined manometric study and pH monitoring after a typical milk meal in a 4-month-old child. The lines indicate reflux episodes with a CCP of different duration. The result shows that refluxes are accompanied by a slight pH decrease only 1 hour after feeding.

demonstration of a gliding or fixed hiatus hernia, assessment of the angle of His, the finding of smooth or pathological pharyngoesophageal deglutition, the course of esophageal peristalsis, and any remarkable features in the epithelium as signs of inflammation constitute the most important information that needs be obtained from a radiological investigation. A further finding is evidence of aspiration of contrast medium during the investigation.

In contrast, the actual evidence of reflux is of less importance because radiological exposure time is short and the true extent of reflux may be overestimated or underestimated. Indirect signs of a pathological reflux include air reflux during the investigation and a positive water siphon test (reflux after taking a large sip of water as a reflux provocation), and the height of the reflux events must be documented.[12] This may yield an evaluation scheme that, however, should be used only if it concurs with a 24-hour pH monitoring.

Twenty-four-hour pH monitoring

This investigation is the gold standard to evaluate frequency and duration of acidic refluxes into the esophagus. The thinnest possible glass or antimony electrodes are introduced by the nasal route, and the ongoing pH values are recorded on a battery-driven recorder. Ideally multichannel probes are used, and pH values in the stomach, the lower esophagus, and the upper esophagus are registered. Thus, a pH drop in the esophagus can be correlated with the pH in the stomach, and the number of acidic refluxes that reach the upper esophagus can also be determined.

All pH drops to <4 for at least 15 seconds' duration (number of refluxes), the time required for normalization of pH and/or the increase of pH to 4 (reflux clearance), the number of refluxes with a clearance time of more than 5 minutes, and the longest reflux are evaluated. Intake of food and the time in lying or upright position are also registered. Different Institutions use different *cutoff values*, which are partly influenced by values in adults. We use the threshold values shown in Table 50.3. The low threshold value of 3% used in infants fed largely with milk takes into account the lower number of acidic refluxes during which the pH drops below 4 (Figure 50.5).

The weakness of the method is the fact that it does not demonstrate refluxes with a neutral pH or mildly alkaline refluxes with an increase in pH.

Combined multiple intraluminal impedance/pH monitoring

Combining over 24 hours the multiple intraluminal impedance (MII) technique with pH monitoring allows us to determine all refluxes and the direction of bolus movements. Thus, even neutral and alkaline refluxes can be recorded (Figure 50.6). This provides a much more informative and valuable assessment of a true reflux compared to simple pH monitoring.[13–15] The technique has been shown to be especially useful in postprandial episodes when the reflux is not acidic or only weakly so as it is in milk-fed newborns and small infants.[16] Furthermore ,it is useful to investigate the efficacy of antiacid therapy. MII can detect microaspirations of nonacid refluxes, which may play an important role in recurrent respiratory tract infection. MII recording with pH monitoring doubles the probability of documenting an association between symptoms and reflux when compared with isolated pH monitoring.[17,18] Thus, the combined MII/pH monitoring has already replaced simple pH monitoring and can be seen as the new gold standard for investigation of reflux disease.

Manometry

Manometric investigations of esophageal function were introduced as a diagnostic procedure quite early in the late 1960s, primarily to measure pressure in the LES. It was presumed at the time that low pressures are responsible for reflux. Initial manometric investigations in newborns and infants appeared to confirm this fact.[19] However, only with the introduction of low-perfusion-low-compliance pumps

Table 50.3 Cutoff values in our gastrointestinal lab

Age (years)	pH < 4 (%)	No. of refluxes	Refluxes > 5 min	Reflux number	Clearance
<1	<3%	<30	<5	<50	<1
>1	<5%	<35	<5	<50	<1

Note: The lower pH % value in children under q year of age is the result of the fact that the gastric acidity is neutralized in infants who are mainly fed with milk products (see also Figure 50.5). "Reflux Number" is "Number of refluxes" + ("Number of refluxes > 5 min" times three).

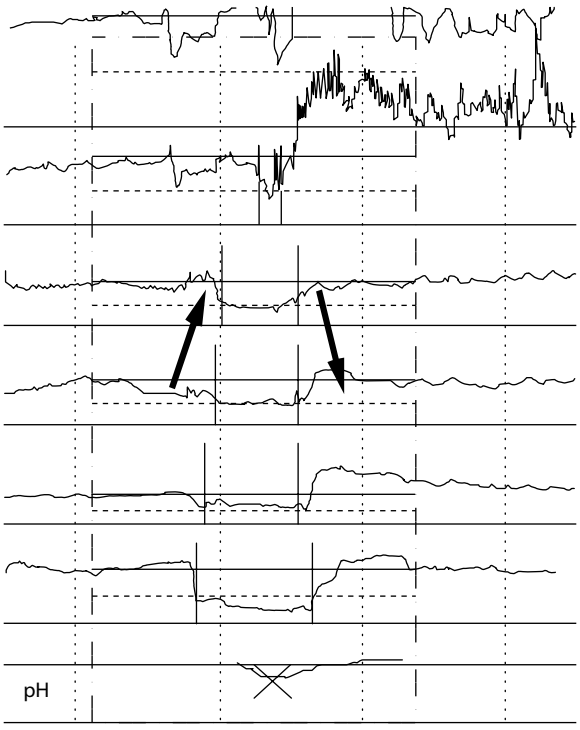

Figure 50.6 Combined impedance and pH monitoring: it shows a short reflux episode with a nonsignificant decrease of the pH in the esophagus, which would not be detected by pH monitoring alone.

did it become possible to obtain reliable pressure values and data.[2]

As mentioned earlier, our investigations performed in the 1970s showed that even at this age, normal pressure values are registered in the LES.[2] Furthermore, manometry is an excellent method to demonstrate the motor function and peristalsis of the esophagus. It shows that reflux of the contents of the stomach occurs during spontaneous transient relaxations of the LES. The manometric sign of these relaxations is the CCP, which is characterized by an increase of the esophageal pressure tracings up to abdominal pressure values and the typical reversal to abdominal pressure fluctuations with respiration (Figure 50.3). Secondary peristalsis causes the refluxed volume to be conveyed back to the stomach. Normalization of the drop in pH is achieved in a stepwise manner by swallowing saliva. In combination with simultaneous pH monitoring, the CCP also allows the investigator to analyze nonacid, neutral, or alkaline refluxes and thus draw conclusions such as those derived from impedance measurement. However, the disadvantage of manometry is that it is a motion-dependent investigation and requires a quiet child. Therefore, it is not suitable as a routine method but is indispensable for scientific questions.

Endoscopy and histology

Investigations with flexible fiber-optic endoscopes and biopsies are invasive investigations but the only way to diagnose esophagitis. Therefore, they are a part of the standard procedure in older patients with GERD but are rarely needed as a routine procedure for reflux in newborn infants.

Briefly, the endoscope is introduced into the esophagus under visual control and is usually extended down to the duodenum. Biopsies from the duodenum and antrum of the stomach are taken routinely. The tip of the device is inverted in the stomach in order to inspect the gastroesophageal junction from below. Under normal circumstances, the esophagus encloses the device tightly, and the aforementioned flutter valve can be seen at the lateral circumference. In contrast, in a hiatus hernia, the cardia is slightly opened, and the investigator is able to see into the herniated stomach, whereas the LES encircles the device higher up.

By withdrawing the endoscope further, the gastroesophageal junction and the Z-line are inspected exactly. In normal cases, the esophageal epithelium is smooth and milky-red in color (grade 0). In the presence of esophagitis, one may find reddening, swelling (grades 1 and 2), striated erosion (grade 3), deep ulceration (grade 4), or stenosis (grade 5). Mild reddening of the mucosa at the distal esophagus is a normal condition. Grades 0–2 are largely prone to subjective assessment and often do not concur with the histological outcome. Therefore, it is essential to take several biopsy specimens, starting 1–2 cm proximal to the Z-line, upward into the upper esophagus. The quality of the biopsied material is of decisive importance for an accurate histological diagnosis. Therefore, an endoscope with the largest possible external diameter should be used to obtain the best possible material with the largest biopsy forceps. The biopsy specimens should be placed on a piece of cork, correctly oriented immediately after the specimen is taken, and then inserted in formalin. An optimal biopsy specimen should include the entire epithelium as well as the basal-cell layer. Thickening of the basal-cell layer and relative elongation of the papilla (due to a thinner epithelial zone) are signs of increased cell turnover and pathological reflux. Evidence of intraepithelial eosinophils then confirms the presence of obvious esophagitis even in the absence of corresponding symptoms. Erosions and ulcerations are, by nature, signs of severe chronic esophagitis. However, in children, this condition is not always associated with unequivocal symptoms. On the other hand, the presence of more than 20 eosinophils per high-power field is a sign of non-reflux-related allergic/atopic disease, which is also known as eosinophilic esophagitis.

Nuclear medicine investigations

Scintigraphic investigations permit the investigator to observe migration of the bolus through the esophagus, any reflux-related aspiration of nuclear medicine tracer material in the lungs, and the measurement of the time taken to empty the stomach after standardized meals. This consists of a solid and a liquid portion, e.g., an egg dish and water. ^{99m}Tc-labeled sulfur colloid is used as tracer. The act of swallowing is visualized in dynamic sequences. After setting the

regions of interest (ROIs), on the one hand, refluxes are registered and on the other hand, the mean time taken to empty the stomach is measured as a time–activity curve. The disadvantage of scinitgraphic study is similar to that of barium radiography: both are short-term investigations that may overdiagnose or underdiagnose reflux numbers. However, a control scan after 24 hours may permit the investigator to document the presence of the tracer in the lung, provided aspiration has occurred in meantime.

CONSERVATIVE THERAPY OF REFLUX DISEASE

A pathological reflux may be considered to exist when the infant has a history of significant regurgitation and flaccid vomiting, suffers from recurrent respiratory tract infections and/or pain, is restless at night, or has other typical symptoms (Table 50.4).[20] As the risk of esophagitis is very low at this age, an endoscopic investigation does not need to be performed if no other indications in consequence of a congenital anomaly are present. In addition to a 24-hour pH monitoring or impedance pH monitoring, a contrast swallow of the esophagus and an ultrasound investigation of the pylorus are usually needed to exclude any pathologies that would hinder spontaneous healing of the reflux disease, such as HH, chronic organoaxial gastric volvulus, gastric stenosis, pylorus hypertrophy, or other anatomic problems.

Since esophageal dysfunction with pathological reflux matures spontaneously in 90% of otherwise normal infants, conservative measurements are the therapy of choice. Former investigations have shown that the prone position with the trunk raised most effectively prevents reflux, because the hiatus is in the highest position.[21] However, the risk of sudden infant death is markedly increased in this position because vomiting during sleep may result in an obstruction of the nose and mouth and cause prolonged apneic spells and sudden infant death syndrome (SIDS). Therefore, the prone position is acceptable if the infant is awake and observed, particularly in the postprandial period. The prone position may be used in children older than 1 year whose risk of SIDS is negligible.[20] Today, the supine position with an elevated trunk or left-side positioning during sleep and elevation of the head of the bed is recommended.[22]

Table 50.4 Symptoms that may be associated with gastroesophageal reflux

Symptoms
Recurrent regurgitation with/without vomiting
Weight loss or poor weight gain
Irritability in infants
Ruminative behavior
Wheezing
Stridor
Unexplained recurrent cough

Source: Adapted from Vandenplas Y et al., Pediatric gastroesophageal reflux clinical practice guidelines: Joint recommendations of the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN), *JPGN* 2009;49: 498–547.

Frequent small-volume meals and thickening of food with rice gruel are recommended and decrease the frequency of regurgitation. There is no clear evidence from the literature that specially manufactured milk formulas are more effective in reducing reflux index scores, but they do reduce vomiting episodes, too.[20,23–25] In most cases, the symptoms abate within the next few months. Prokinetic therapy is not anymore recommended in children.[20]

As mentioned previously, the disappearance of the symptoms does not necessarily mean that there is no more reflux; it might just not reach the mouth. Therefore, at the end of the first year, a control 24-hour impedance/pH monitoring should be performed to definitively exclude persistent reflux.[26,27]

About 10% of these children still have pathological results and need further treatment and controls. In these patients addition of acid-suppressive therapy is usually indicated, e.g., proton pump inhibitors (PPIs). Experience with PPIs in 10 infants with unquietness/pain-related gastroesophageal reflux showed that the number of acidic refluxes was significantly reduced, but the total number of refluxes was unchanged.[28] PPIs only decrease the acidity of refluxate.[29] Thus, vomiting, aspiration during sleep, and chronic respiratory tract infections may still continue, despite PPI therapy. Thus, more studies are needed to determine which infants and children should be treated with PPIs.[20,30] When administering any form of antiacidic medication for the treatment of reflux, one should be aware of the fact that the production of gastric acid is largely reduced, and the consequences on the intestinal flora of infants and children have not been evaluated so far.[20]

Our experience has shown that spontaneous normalization of the esophageal function may still occur beyond the first year, up to the age of 3–4 years, and conservative treatment can be continued if the symptoms are minimal and the parents want to avoid surgery. However, after this time, a spontaneous maturation of the function cannot be expected, and surgical therapy is indicated. It has been shown that in these patients, pathological reflux patterns continue till adulthood.[7] In contrast, it has been shown that preterm birth is associated with esophagitis in childhood, but being small for gestational age is associated with esophagitis even up to adolescence.[31]

SURGICAL THERAPY

As mentioned previously, surgery of reflux is not indicated in most newborns and infants due to the spontaneous maturation of the esophageal function within the first year of life. However, there is a small group of patients in which any trials of conservative therapy are ineffective, even when treated under in-hospital supervision. Additionally,

the process of spontaneous normalization of a pathological reflux cannot be expected in babies after correction of an esophageal atresia, diaphragmatic hernia, congenital HH, or even upside-down stomach, organoaxial gastric volvulus, and some other congenital anomalies. In these children, surgical procedures are indicated in order to avoid the long-term sequelae of unphysiologic neutralization of gastric acid with PPIs, which are problematic.

The strategic principles of reflux surgery consist of creating an intra-abdominal portion of the esophagus and a complete (Nissen) or partial plication (dorsal Toupet, ventral Thal) of the gastric fundus around the esophagus.[32] The standard approach today is by laparoscopy, showing a low recurrence rate (3%) during long-term follow-up.[33] Recurrence rate increases up to 12% in children with neurological impairment, esophageal atresia, or congenital diaphragmatic hernia.[34] Therefore, Hassall[35] recommends treatment with PPI as a safe alternative to surgery in many cases.

In fact, recurrent reflux has been observed with all three surgical methods (Table 50.2).[36–38] It is related to the natural agitation in this region due to the movement of the diaphragm during respiration and due to the significant shortening of the esophagus that occurs during swallowing.[39] Further risk factors for recurrence are severe rumination and regurgitation, which occur in some cerebral-handicapped children.[40] Rare complications after a Nissen procedure may occur in patients with a rather tight fundoplication and the inability to vomit, gas bloat syndrome, or dumping.

A rarely used method that might be useful in a patient with a very small stomach is the Collis gastroplasty, for which the His angle is deepened parallel to the esophagus with a stapler. The lengthened fundus is then used for a Nissen, Toupet, or Thal plication around the elongated esophagus.

The gastroesophageal dissection is an other method that is useful in rare cases of severely cerebral-handicapped infants with massive rumination and recurrent GERD.[41] The esophagus is detached from the stomach and anastomosed to a Roux-en-Y jejunal loop. Orally ingested food is thus diverted directly into the jejunum, and recurrent reflux or rumination is rendered impossible.[42]

In the last few years, a number of new technical methods have been introduced for the treatment of reflux in adults, such as creation of a mucosal fold by an intraluminal stapler, radio-wave damage of the cardia (Stretta procedure), or endoscopic submucosal injection of foreign material (Enteryx). Experiences in children are rare, and long-term results are lacking [43–46]

SPECIAL PROBLEMS OF REFLUX IN THE NEWBORN AND INFANT

Laryngopharyngeal reflux

Chronic microaspiration of acidic reflux during the day and/or night may cause laryngeal symptoms such as hoarseness, the urge to cough, and dysphagia. Each endoscopic investigation is incomplete if the larynx is not inspected. Reddening, ulcerations, or pseudopolyps on the vocal cords are typical signs of laryngeal reflux. However, as mentioned previously, these findings are very rare in this age group as long as the babies are mainly fed with milk. As regards therapy, medication with PPIs is recommended to prevent contact of gastric acid with the laryngeal folds.

Reflux-associated infections of the respiratory tract

Aspiration of acidic or nonacidic reflux may be the cause of recurrent respiratory tract infections and pneumonia. Other causes such as cystic fibrosis, aspirated foreign bodies, H-type fistulas, or other malformations of the respiratory tract must be excluded. In cerebral-handicapped children, disruption of the pharyngoesophageal transport—disturbed swallowing—is another well-known cause of recurrent aspiration.

Diagnosis is not simple, except when the radiological investigation shows aspiration of the contrast material during reflux phases. Neither bronchoalveolar lavage nor nuclear medicine investigations are unequivocal. Twenty-four-hour combined MII/pH monitoring with several recording points along the esophagus provides indirect signs when a large number of refluxes extends into the upper esophagus.[47] If evidence of recurrent reflux-associated aspiration and chronic unexplained cough is obtained, surgery is indicated.

Reflux and apnea syndrome

Apnea and SIDS are the most common causes of death between the ages of 2–6 months. The association of reflux with apneic spells has been investigated, with unequivocal results.[48] Some studies have not proved a temporal relationship between GER and apneas.[49,50] Although an increased rate of GER was observed after feeding in preterm infants, a corresponding increase of apneic spells was not found. Our investigations with manometry and pH monitoring in infants with pathological sleep apneas have not shown that acidic refluxes are directly causing apneic spells. However, we did register a markedly delayed maturation of motor function of the esophagus in babies with sleep apnea or apparent life-threatening events (ALTEs).[5] Further studies have shown that infants investigated due to a pathologic sleep-apneic pattern frequently also have pathological reflux, whereas infants with a primary history of pathological reflux have no remarkable apneic spells.[51] These investigations support the hypothesis that infants with sleep apnea syndrome or ALTE suffer from a deeper localized underlying immaturity of regulation centers in the brain stem, while the causes for a delay in the maturation of the esophageal motor function are localized in higher brain stem regions and therefore not necessarily associated with disorders of respiratory regulation.[2]

Hiatal hernia

Any upward gliding of portions of the stomach into or above the esophageal hiatus are called hiatal hernia. A gliding HH is rare in newborns and infants, but one cannot expect a spontaneous normalization of this anatomic malformation. The previously used term *forme mineure* for minimal HH in infants is not anymore considered a pathology but is known as a normal finding of the special anatomy of the gastroesophageal junction in this age group.

Paraesophageal hernias are not-so-rare findings after fundoplication. A part of the stomach slips through the hiatus into the chest, lateral to the gastroesophageal junction. If a small postoperative paraesophageal hernia is combined with reflux or any other symptoms, surgical correction is indicated. A congenital form of paraesophageal hernia is the upside-down stomach in the newborn, which is a more or less complete displacement of the stomach into the chest while the gastroesophageal junction remains in normal position.

Esophageal atresia and diaphragmatic hernia

The lower segment of the esophagus in patients with esophageal atresia is characterized by an abnormal or absent propulsive peristalsis.[52] Due to the absent peristalsis, refluxed material remains for a prolonged time in the esophagus, and volume as well as acid clearance are significantly prolonged, especially during sleep. The long acid clearance time may cause already in this age group a chronic esophagitis. A spontaneous normalization of the pathology cannot be expected; therefore, surgical correction is usually necessary.

Children with congenital diaphragmatic hernia suffer often from a pathological reflux due to the abnormal anatomy of the gastro–esophageal–diaphragmatic anatomy.[53,54] Early fundoplication is indicated because a spontaneous normalization of the disturbed function cannot be expected.

REFLUX IN NEUROLOGICALLY IMPAIRED CHILDREN

In patients with severe neurological impairment, GERD is a common disorder that may lead to a number of complications such as esophagitis, esophageal stenosis, anemia, and/or Barrett esophagus. Although these symptoms usually become clinically evident only in later childhood, vomiting, recurrent respiratory tract infections, as well as failure to thrive are, in small babies, are strong indicators that the underlying pathology is accompanied by a significant reflux problem.[55] Manometric studies show that these children suffer not from a sphincter insufficiency but from too many spontaneous LES relaxations. These findings support again the hypothesis that pathological reflux is strongly connected with a dysfunction of the regulation centers in the brain. Whether conservative therapy including PPIs, a fundoplication (with or without a button gastrostomy), or an esophagogastric dissection is needed has to be decided on an individual basis considering the living quality and circumstances of the child.

CONCLUSION

GER is common in neonates and small infants. It is caused in most cases not by an insufficient LES but by a delay in the development of the esohageal function characterized by many spontaneous relaxations of the LES. In more than 90% of babies, a spontaneous maturation of the esophageal function can be expected till the end of the first year of life, and therefore, unspecific conservative measurements are usually sufficient. In contrast, babies with severe and recurrent complications of reflux, e.g., recurrent respiratory tract infections, and/or congenital malformations usually need surgical therapy by semicircular or complete fundoplication.

Pyloric atresia and prepyloric antral diaphragm

ALESSIO PINI PRATO, VINCENZO JASONNI, AND GIROLAMO MATTIOLI

PYLORIC ATRESIA

Introduction

Gastric outlet obstruction in the newborn may be due to pyloric atresia (PA), antral web, or hypertrophic pyloric stenosis. The latter is most common cause of gastric outlet obstruction.

PA is a rare congenital malformation representing less than 1% of all atresias and diaphragms involving the gastrointestinal tract.[1–3] Up to 50% of these patients have associated abnormalities, of which epidermolysis bullosa (EB) is by far the most common.[1,4–6] Familial occurrence of PA has been reported.[5–7] In particular, Puri and coworkers[7] first described PA in three consecutive siblings in a family.

Etiology

Though a sure etiology is still unknown, mucosal desquamation leading to gastric outlet obstruction has been suggested to play a role, mainly in patients with associated EB.[8] Junctional epidermolysis bullosa (junctional EB) associated with pyloric atresia (EB-PA: "OMIM [Online Mendelian Inheritance in Man]" 226730) represents a rare congenital disorder also known as Carmi syndrome, named after the author who described, in 1982, the association of aplasia cutis and PA[9] and, later on, in 1998, suggested the existence of an autosomal recessive inherited disease including EB, PA, and aplasia cutis congenita,[10] in which mucocutaneous fragility is associated with congenital gastric outlet obstruction. This association is usually fatal during the first few weeks or months of life, even following surgical correction of intestinal obstruction. Mutations in the genes encoding α6β4 integrin (ITGA6 and ITGB4 genes) and plectin (PLEC gene) have been identified in a number of patients with EB-PA.[8,11–13] Regardless of whether or not it is associated with epidermolysis, several authors agreed that there is strong evidence to support an autosomal recessive model of inheritance for PA.[14,15]

Pathology

There are three main different types of pyloric obstruction: (1) type A, pyloric membrane or web; (2) type B, longitudinal segmental atresia (i.e., pylorus replaced by fibrotic tissue); and (3) type C, PA with a gap between the stomach and the duodenum (Figure 51.1). Table 51.1 shows the incidence of different types of pyloric obstruction.[2,3]

History and physical examination

Prenatal diagnosis of PA can be suspected when polyhydramnios is present and associated with a dilated stomach. Prenatal diagnosis of PA and EB can be performed in pregnancies at risk for recurrence of this syndrome. However, some sonographic signs suggest the possibility of significant cutaneous desquamation and blister formation in a fetus, especially when there is positive amniotic acetylcholinesterase coupled with elevated alphafetoprotein.[16] Since 2009, prenatal magnetic resonance imaging (MRI) has been used to confirm the diagnosis, but its utility remains unclear.[17,18]

Presentation

The newborn with complete pyloric obstruction presents shortly after birth with persistent nonbilious vomiting and epigastric distension.[19] There is no significant gender predominance, and there is a high proportion of infants with low birth weight.[5,20,21] Recently, Al-Salem and coworkers[5] reported an incidence of over 65% of prematurity in a series of 20 patients with PA.[5] Respiratory problems are common, and dyspnea, tachypnea, cyanosis, and/or excessive salivation may suggest esophageal atresia.[22] Scattered reports of the association between PA and esophageal atresia have been described.[23,24]

Delayed diagnosis of PA can determine gastric perforation, although this complication has also been reported as early as 12 hours postdelivery.[25] See Table 51.2 for clinical features.[2,3]

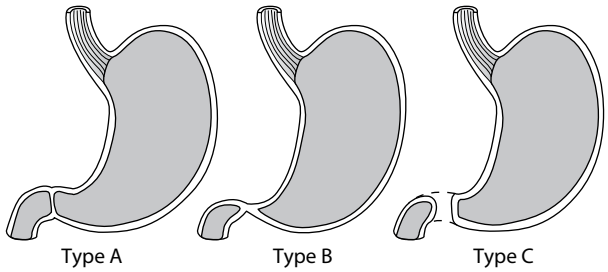

Figure 51.1 Anatomical varieties of congenital pyloric obstruction: type A—membranous pyloric obstruction; type B—longitudinal segmental atresia; type C—pyloric aplasia.

Table 51.1 Incidence of the different pyloric atresia types (*n* = 140)

Type of atresia	n	%
Membranous (type A)	77 cases	57
Atresia (type B)	46 cases	34
Aplasia (type C)	12 cases	9
No data	5 cases	3.5

Diagnosis

A plain x-ray of the abdomen will usually confirm the clinical diagnosis. X-ray (Figure 51.2) will show a severely dilated stomach without air below.[26] Contrast study, although unnecessary, will confirm complete obstruction at the pyloric region. The radiological diagnosis is based on the identification of three radiological signs: the single gas bubble sign, the absence of beak sign (typical of hypertrophic pyloric stenosis), and the presence of the pyloric dimple sign on a contrast study.[27] The single gas bubble sign is not specific to the diagnosis of PA, but it is an indicator of a gastric outlet obstruction. The ultrasonographic examination can be helpful and demonstrates the absence of normal pyloric muscle and canal, which is specific for the diagnosis of this entity.[27]

Management

Depending on the type of pyloric obstruction, different operative procedures are used. The best results from operative treatment of membranous obstruction are obtained by excision of the membrane associated to pyloroplasty according to Heineke–Mikulicz or Finney.[1–4] Transgastric excision of the pyloric membrane without pyloroplasty has also been reported.[28] In case of longitudinal segmental atresia, the operative method depends on the length of the atresia. When the atresia is short, a Finney pyloroplasty can be carried out. For longer atresia, the procedure of choice is excision and end-to-end gastroduodenostomy.[4] Gastrojejunostomy is not recommended, due to the high mortality rate[4] and because of the risk of marginal ulcer and blind loop syndrome.

Table 51.2 Clinical features of pyloric atresia (*n* = 140 patients)

Symptoms and signs	Occurrence (%)
Bile-free vomiting	100
Single stomach bubble (one bubble) on x-ray	98
Distended epigastrium	68
Polyhydramnios	63
Birth weight <2500 g	53
Prematurity	45
Jaundice	21
Peristaltic movements in the epigastrium	18
Hemorrhagic vomiting	12

Preoperative management

Usually, newborns are referred to the hospital and admitted within the first 48 hours of life. They are generally in good physical condition, except those with EB. Preoperative preparation should consist of gastric decompression by nasogastric tube insertion. An intravenous infusion should be started to correct dehydration, electrolyte imbalance, and metabolic alkalosis observed in most cases. A central

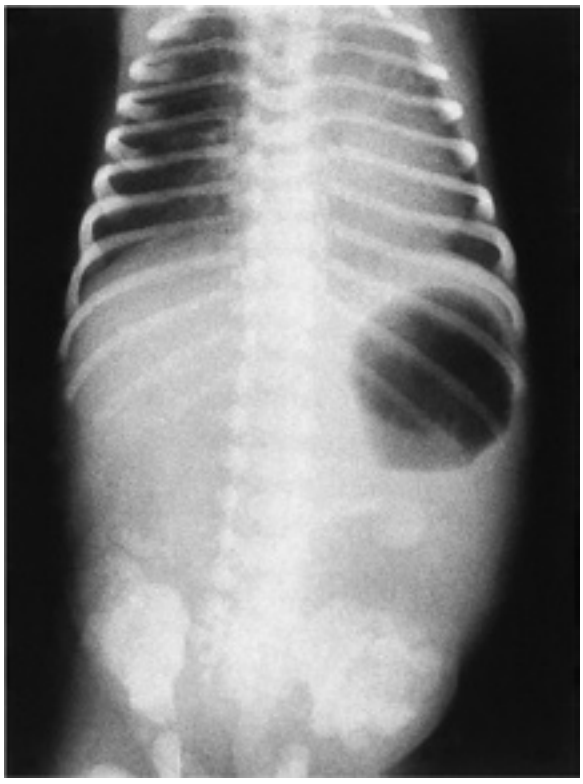

Figure 51.2 Abdominal x-ray showing absence of air beyond the stomach.

line should be inserted to administrate parenteral nutrition and long-term medical treatment specifically in those newborns with associated EB.

Operative technique

LAPAROTOMY

A transverse abdominal incision is made 2 cm above the umbilicus, starting just left of the midline and leading to the right in a skin crease for about 5 cm (Figure 51.3a). The abdominal cavity is opened in the line of the incision. Careful exploration and search of other intestinal atresias are performed at this site.[15]

IDENTIFICATION OF THE SITE OF OBSTRUCTION

During the procedure, it may become difficult to identify the exact disease; therefore, a gastrotomy can be helpful in this regard.[19] Another way to find the exact location of the web and prevent the gastrotomy can be achieved by placing a firm 12–14 Ch. nasogastric tube, to be advanced up to the region of the obstruction.[29]

PYLOROPLASTY

This procedure is indicated for membranous pyloric obstruction (type A) and short atresia (type B).[4,7,14]

After identification of the pylorus, a longitudinal incision is made with cutting diathermy or scissors, starting on the gastric side of the pylorus to the duodenum (Figure 51.3b). A blunt dissecting forceps, which is inserted into the lumen, is useful at this stage. Care must be taken that no inadvertent damage is done to the posterior wall of the stomach or duodenum. The total length of the incision should be 1.5–2 cm, extending approximated 1 cm on the gastric side and 1–1.5 cm on the duodenal side of the pylorus; it should be preformed on the midline between the greater and lesser curvatures of the stomach and superior and inferior borders of the duodenum. The greater length on the gastric side is necessary because of the thicker gastric wall in order to properly align both margins of the incision in the transverse direction. The membrane is excised circumferentially and the mucosa approximated with 5-0 absorbable sutures (Figure 51.3c). The duodenal lumen is inspected, and a catheter is pushed down to exclude further distal atresias. The longitudinal incision is then closed transversely in layers after meticulous hemostasis (Figure 51.3d).

CLOSURE OF ABDOMEN

Gastrostomy is not strictly necessary but can be considered in certain instances. In particular, it could be beneficial for

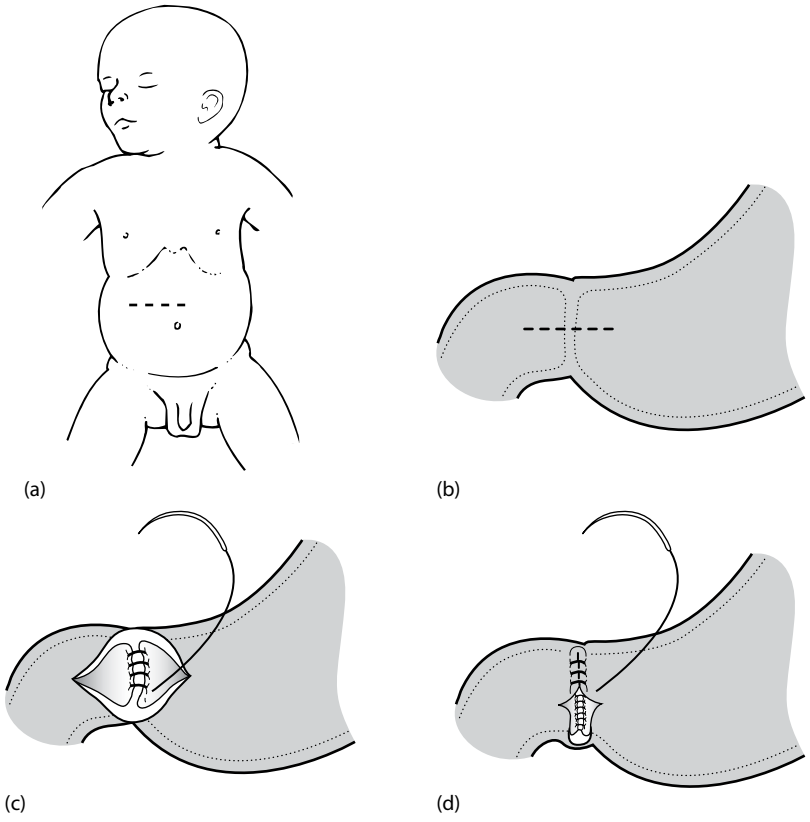

Figure 51.3 Operative technique of pyloroplasty. **(a)** Skin incision. **(b)** Pyloric longitudinal incision. **(c)** Incision of the membrane and suture. **(d)** Longitudinal incision closed transversely.

patients with EB-PA in order to avoid the need for prolonged nasogastric tube maintenance. The abdomen is closed in two layers, and the nasogastric tube is left in the stomach for decompression.

LAPAROSCOPIC APPROACH

To date, only Son and Hoan[30] have reported a complete laparoscopic treatment of a newborn with EB-PA. The authors described a successful and satisfactory outcome and suggested laparoscopy as an alternative option to the conventional laparotomic procedure. Although newborns have high sensitivity to insufflation, pneumoperitoneum is usually well tolerated provided that CO_2 pressure is maintained below 8 mmHg.[31] An advantage of laparoscopy in case of EB-PA is the reduced wall trauma and subsequent lower likelihood to develop mucocutaneous lesions related to junctional EB.

Postoperative management

Parenteral nutrition should be discontinued when the patient tolerates oral feeding well. A nasogastric tube should be kept in the site for 2–3 days to maintain gastric decompression or even longer if there are signs of delayed gastric emptying. Intravenous broad-spectrum antibiotics are administered intraoperatively and should be discontinued after 3−5 days, according to the patient's condition.

Complications

Complications are uncommon but include strictures, leakage, adhesions, infections, and bleeding as with any other abdominal surgery. Wound dehiscence and/or infection can occur, particularly in patients with EB.

Long-term results

Early diagnosis and surgical intervention with adequate neonatal supportive care significantly improve the survival of pure PA. Mortality has been associated with delayed diagnosis,[12,13] but it is mainly due to the associated malformation. Survival and long-term results are excellent in isolated forms of PA. Mortality rate ranges between 20% and 60%, and the majority of fatal cases are those with EB and/or other multiple intestinal atresia.[5,6,24,32] On the grounds of these considerations, Rosenbloom and Ranter[33] suggested a nonoperative management of PA, unless the skin disease is responsive to treatment. On the other hand, Hayashi et al.[34] reported long-term survival in four out of five patients with EB-PA. A comprehensive review from Dank and coworkers in 1999[35] reported that 51 out of 70 patients with EB-PA had been operated on worldwide, with a long-term survival of roughly 31%. Not surprisingly, survival was mainly observed in patients with mild forms of epidermolysis.

PREPYLORIC ANTRAL DIAPHRAGM

Introduction and etiology

Prepyloric antral diaphragm is a rare anomaly involving a submucosal web of gastric tissue covered by gastric mucosa and found in the distal gastric antrum. A total of about 150 cases have been reported, divided between pediatric and adult age ranges.[36] Reports have suggested both acquired and congenital forms, citing epidemiological and histological evidence.[37]

Pathology

There are three groups of patients: a neonatal group with complete or partial obstruction, a group presenting later in childhood, and a group not diagnosed until later in life.[38] Significant associated abnormalities are noted in about 30% of children with antral web, including Down syndrome, gastrointestinal issues, and cardiovascular malformations.[37,39]

History, presentation, and diagnosis

In the neonatal group, nonbilious vomiting is the predominant presenting symptom. Other symptoms include apnea, cyanosis, and no weight gain.[38] Older children complain of abdominal pain, vomiting, fullness after eating, and bloating. Prolonged retention of foreign bodies can lead to the diagnosis is older children.[40] In the elderly group, the clinical history consists of episodic cramping, epigastric pain or fullness following meals, and intermittent vomiting. There is one report describing a case diagnosed in the eighth decade of life.[41]

The diagnosis of antral web with a central aperture is with a barium meal in 90% of cases.[37] The typical appearance of a web in an infant is a thin, membranous septum, projecting into the antral lumen, perpendicular to its longitudinal axis 1–2 cm proximal to the pylorus (Figure 51.4a).

Gastroscopy has recently been noted to be of use in confirming clinical and radiological evidence of the web in

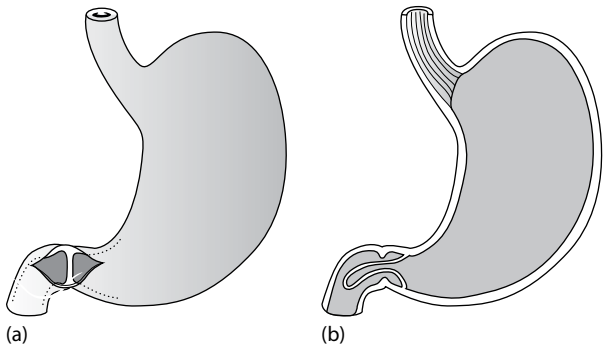

Figure 51.4 **(a)** Prepyloric antral web. **(b)** Wind-sock antral membrane protruding into the duodenum.

older infants and in children.[42] Features of the web include the following:

- A small fixed central aperture surrounded by gastric mucosa that is smooth and devoid of folds.
- No change in the opening size of the web with peristalsis.
- The gastric wall proximal and distal to the web is seen to contract normally.[43]

Management

Preoperative and postoperative management does not significantly differ from that of PA. Surgery for partially obstructing antral web consists of excision of the web, combined with pyloroplasty if the web is very close to the pylorus (same as PA). Furthermore, at operation, it is important to pass a Foley catheter distally to the stomach, and then to inflate the balloon and withdraw the catheter.[29] Wind-sock pyloric and antral membranes protruding into the duodenum have been reported (Figure 51.4b) and would be missed at laparotomy by simple inspection of the gastric lumen.[44] Other methods are reported. Most noticeably, some reports described successful endoscopic transection using a standard papillotome[45] and forceful dilatation of antral membrane without pyloroplasty.[46] Recently, Bing and coworkers reported successful laparoscopic-assisted treatment of prepyloric webs in a series of three infants who were treated by gastrostomy and resection.[47] No similar reports have been published so far.

Medical treatment has been reported with success in infants without pronounced obstruction.[48] While this concept of conservative management is supported by some surgeons, the majority of the literature preferred the surgical correction of this entity, which will reduce and prevent morbidity and unnecessary counseling in this group of babies and children.[4,36]

Complications and long-term results

Complications do not significantly differ from those of isolated PA.

Infantile hypertrophic pyloric stenosis

PREM PURI, BALAZS KUTASY, AND GANAPATHY LAKSHMANADASS

INTRODUCTION

Infantile hypertrophic pyloric stenosis (IHPS) is the most common condition requiring surgery in the first few months of life. It is characterized by hypertrophy of the circular muscle of the pylorus, causing pyloric channel narrowing and elongation. The incidence of IHPS varies widely with geographic location, season, and ethnic origin.[1] The incidence has been reported to be approximately 0.5–2 per 1000 live births.[2–4] A remarkable decline in the incidence of IHPS has been reported during the 1990s and early 2000s in Western countries.[2,3] Environmental changes rather than genetic ones are likely to explain this development (e.g., increased breastfeeding rate).[3,5] Boys are affected five times more often than girls, and the ratio of affected boys to girls was relatively constant throughout the past decades.[2]

ETIOLOGY

Although earlier diagnosis, advances in fluid and electrolyte therapy, and pediatric anesthesia have reduced the mortality to practically zero, the exact etiology of pyloric stenosis is unknown.[5] This condition is usually classified as a congenital disorder. It is almost unknown in stillbirths, associated anomalies are very uncommon, and the patient usually presents with vomiting after the second week of life; changes in disease incidence over the past two decades indicate that environmental factors are also important.[3,5] Rollins et al.[6] measured pyloric muscle dimensions on ultrasonography in 1400 consecutive newborn infants. Nine of these infants subsequently developed pyloric stenosis and were operated upon. Their pyloric muscle measurements at birth were all within the normal range. This study clearly showed that congenital pyloric muscular hypertrophy is not present in babies who later develop pyloric stenosis.

The occurrence of IHPS has been associated with several variables such as genetic, environmental, and mechanical factors. The pyloric sphincter, a zone of intermittently increased pressure, is able to contract tonically and phasically and produce an effect on gastric emptying. Pyloric sphincter function and motility is under a complex control system that involves the enteric nervous system, gastrointestinal (GI) hormones, and interstitial cells of Cajal (ICC); these pathways have been investigated in IHPS, and abnormalities in hormonal control, extracellular matrix (ECM), smooth muscle fibers, growth factors, and ICC have been implicated in the pathogenesis of the disease.

EXTRINSIC FACTORS

Various environmental and mechanical factors have been proposed as potential causes of IHPS. Significant correlation has been found between higher pesticide (insecticides and herbicides) use in the families' living area and the development of IHPS.[7] Maternal smoking has been shown to double the risk for IHPS.[8] The maternal age has been related with IHPS, and the following results have been found: there is a significantly increased risk for IHPS with young maternal age (<20 years), and a significantly decreased risk with maternal age 30 years and older.[9] Firstborns are at 1.8 increased risk for IHPS.[10] Very preterm birth was associated with a more than twofold increased risk for IHPS, and interestingly, premature infants with IHPS have a higher female predominance.[2,11,12] Caesarean delivery was significantly associated with an increased risk for IHPS.[2] The mechanism for how caesarean delivery could trigger the development of IHPS is unclear. Infants born by caesarean section are known to have differences in the gut flora, which may lead to IHPS.[2] Another potential link between caesarean section and IHPS could be the delayed start of breastfeeding associated with caesarean delivery.[13]

Recently, it has been demonstrated that infants who are bottle-fed has a 4.6-fold increased risk of developing IHPS compared with infants who are not bottle-fed.[3,14] Under the hypothesis that breast milk confers protection against IHPS, one suggestion has been that the presence of high levels of hormones such as vasoactive intestinal peptide in human milk favors pyloric relaxation.[14,15] Breast milk also has lower osmolarity, which could provide better gastric emptying.[14,16]

However, even within 14 days of bottle exposure, among the infants both breast- and bottle-fed, the risk is increased.[14] This observation suggests that limited exposure to bottle-feeding quickly results in a higher risk of IHPS.[14] It has been shown that formula has a higher level of whey and particularly casein proteins than breast milk, and is likely more difficult for the infants to digest causing slower gastric emptying.[14,16] Furthermore, infants fed by bottle have higher serum gastrin levels, which can be associated with pylorospasm.[3,15] Formulas have been improved over time and now approach the composition of breast milk. This could be a contributing reason for the decrease in IHPS incidence.[14]

Lund at al.[17] have found in their nationwide cohort study that macrolide (erythromycin or azithromycin) use in infants for different types of infection is associated with a strongly increased risk of IHPS, including a 30-fold increased risk with use during the first 2 weeks after birth and a lower, but significantly increased threefold risk with use on days 14 to 120. The risk of IHPS is increased more than threefold with maternal use of macrolides during the first 2 weeks after birth, but is not increased with macrolide use thereafter. They found no evidence of an association between IHPS and maternal use of macrolides during gestational weeks 0 to 27, but a possible modest association with use during weeks 28 to birth. It has been shown that both erythromycin and azithromycin are gastrin motilin receptor agonists.[18] Activation of these receptors by macrolides with consequent increased pyloric contractions has been hypothesized as a possible cause of IHPS.

A growing body of research has hinted at seasonality in IHPS epidemiology.[19] Most investigations have observed a peak summer incidence.[20–22] Others have found bimodal spring–autumn peaks[23] or winter peak,[24] or have failed to demonstrate seasonality at all.[25,26] The seasonality has raised the suspicion of an infectious etiology for IHPS.[19] In the adult patient population, resolution of pyloric stenosis after eradication of *Helicobacter pylori* has been found.[27] However, no direct link between IHPS and *H. pylori* has been discovered.[19] Any evidence of association between IHPS and common neonatal respiratory and GI viruses has also not been found.[19]

In a small number of cases, IHPS has been believed to develop as secondary effect to a primary gastric outlet obstruction by mechanical factors. Transpyloric feeding tube, an antral polyp, and a pyloric cyst have been associated with IHPS.[28]

GENETICS

As IHPS tends to run in families, genetic factors have been implicated in its etiology. IHPS is relatively rare in babies of African, Indian, and Chinese extraction.[29,30] Boys are affected five times more often than girls.[2,6] In a population-based cohort study of almost 2 million children,[31] there was a nearly 200-fold increased risk in monozygotic twins, a 20-fold increased risk among siblings. Familial aggregation of IHPS was pronounced even in more distant relatives. The aggregation was observed on both the maternal and paternal sides of the families and irrespective of sex of the cohort member and sex of relatives. Heritability was estimated to be 87%. In a follow-up study extending over 45 years, Carter and Evans[32] found that 5%–20% of the sons and 2.5%–7% of the daughters of affected patients developed IHPS. Sons and daughters of affected female patients had three to four times the incidence of IHPS than sons and daughters of affected male patients.[33] It seems that familial aggregation is primarily explained by shared genes.[31] However, the condition does not follow classic mendelian modes of inheritance.[31] A multifactorial threshold model has been discussed that suggests that IHPS is caused by polygenic inheritance of genes that are modified by sex and environmental factors.[31]

IHPS has been associated with a number of inherited genetic syndromes such as Smith–Lemli–Opitz and Cornelia de Lange, as well as chromosomal abnormalities including partial trisomy of chromosome 9, partial trisomy of chromosome 13, and partial monosomy of chromosomes 8 and 17.[34]

Although a specific gene responsible for IHPS has not yet been discovered, several susceptible loci have been identified, such as 3p25, 16p12-q13, 16q14, 11q14-q22, 11q23, and Xq23 involving NOS1, APOA1, NKX2-5, and MBNL1 genes.[35–39] In view of the implication of the enzyme neuronal nitric oxide synthase (nNOS) in the pathogenesis of IHPS, NOS1, the gene encoding nNOS on chromosome 12q, has been investigated by linkage analysis and evaluation of nNOS mRNA expression[40] and suggested as a susceptibility locus. APOA1 encodes apolipoprotein A-1, a major protein component of high-density lipoprotein (HDL) in plasma, which has been found to be associated with levels of circulating cholesterol.[37] In IHPS, lower cholesterol levels have been found at birth in infants who went on to develop IHPS compared with matched controls who did not develop the disease.[37] A number of previous findings would be consistent with low lipid levels representing an important risk factor for IHPS: The protective effect of female sex could at least partly be due to higher cholesterol levels, since it is well known that levels of LDL cholesterol and HDL cholesterol are, on average, higher in newborn girls compared to boys; IHPS risk associated with bottle-feeding could in part be caused by insufficient lipid levels since bottle-feeding is known to be associated with lower total and LDL cholesterol levels in infancy; and cholesterol has an essential role in nervous system including enteric nervous system development.[37] NKX2-5 encodes the NK2 homeobox 5 transcription factor, which has been shown to have a critical role in pyloric sphincter development.[39,41,42] It has been reported that Sox9 is critical for embryonic pyloric smooth muscle development.[41,42] Nkx2-5 and Gata3 are required for pyloric sphincter morphogenesis, and both directly or indirectly regulate Sox9.[42,43] It has been suggested that some forms of IHPS can result from overexpression of NKX2-5 at the pylorus.[42] MBNL1 is a double-stranded RNA binding protein, and it is a member of muscleblind protein family, which are important regulators of alternative splicing.[38,39] In the early

postnatal period, splicing transitions from fetal to adult protein isoforms are essential for the extensive remodeling of muscle tissue that occurs as a part of normal development.[44] In studies of mouse heart and skeletal muscle development, Mbnl1 has been shown to control a set of temporally correlated splicing transitions that occur within the first 3 weeks of postnatal life.[45,46] The intriguing observation that IHPS occurs almost exclusively between 2 and 8 weeks after birth points to a possible role for misregulation of MBNL1 controlled splicing transitions in the etiology of IHPS.[38]

ABNORMALITIES OF HORMONAL CONTROL

The human pylorus is characterized by a zone of elevated pressure that relaxes with antral peristalsis, contracts in response to intraduodenal stimulation, and prevents the retrograde movement of duodenal contents into the stomach.[47] The hormonal control of the pyloric sphincter function by mediators such as gastrin, somatostatin, cholecystokinin, and secretin has been reported to be the same as in other GI sphincters.[48] Since Dodge successfully induced pyloric stenosis by prolonged perinatal maternal stimulation with pentagastrin in approximately one-half of a litter,[49] together with the finding of elevated serum gastrin levels in infants with IHPS,[50] and growing evidence of strong relation between a gastrin motilin agonist macrolide use and increased incidence of IHPS,[17] much attention has been paid to the role of gastrin in the pathogenesis of IHPS. It has been suggested that repeated hyperacid stimulation of the duodenum induced by gastrin evokes repeated pyloric sphincter contractions with work hypertrophy of the pylorus.[51] However, Janik et al.[52] failed to induce pyloric stenosis in other species by prenatal administration of pentagastrin. Some investigators found significantly high plasma gastrin levels in affected infants compared to healthy controls,[50,53] whereas others failed to confirm this finding.[54,55] Since raised serum gastrin levels return to normal following pyloromyotomy, it is believed that they are secondary to antral stasis.[54]

Prostaglandins are produced in response to acid secretion and have a role in GI motility as well as cytoprotective and trophic effects. Prostaglandins PGE2 and PGE2a in the gastric juice have been found to be elevated in IHPS as compared with controls, and based on the belief that they influence pyloric contraction, it has been suggested that these substances may be responsible for pylorospasm and pyloric hypertrophy.[56] Although the finding of elevated PGE2 in IHPS has been confirmed, evidence on prostaglandins causing relaxation of circular smooth muscle has challenged the hypothesis that prostaglandins cause pyloric hypertrophy.[57] However, prostaglandin treatment for cyanotic congenital heart disease has been shown to induce antral hyperplasia and gastric outlet obstruction that mimics IHPS.[58] Moreover, this gastric outlet obstruction can be transient and resolve spontaneously when prostaglandin treatment has been stopped.[59]

ABNORMALITIES OF PYLORIC INNERVATION

Although the smooth muscle sphincter tone is myogenic, contraction and relaxation are under neural control via activation of excitatory and inhibitory pathways, respectively. Sympathetic stimulation is believed to exert an excitatory effect on the pyloric sphincter, while parasympathetic stimulation has either an excitatory effect via cholinergic neurons or an inhibitory effect via nonadrenergic noncholinergic neurons.[60]

The innervations of the musculature regulating motility are particularly dense at the level of the smooth muscle sphincters of the GI tract.[61] Relaxation of the sphincter is accomplished by activation of inhibitory motor neurons.[62] As a defect in pyloric relaxation has been thought to be responsible for the gastric-outlet obstruction and development of pyloric muscle hypertrophy, many investigators have sought evidence for neural abnormality in specimens of IHPS that may explain the failure of pyloric muscle relaxation.[5] Earlier studies concentrated on abnormalities in the myenteric plexus[63–70] and more recent studies with advances in laboratory techniques and equipment have focused on the glial cells, the synaptic function, and the neurotransmitter status in both the myenteric plexus and pyloric muscle layers.[40,70–81]

Ganglion cells

Many investigators have reported conflicting morphologic findings as regards ganglion cells in the myenteric plexus in IHPS. A number of early authors found decreased numbers of ganglion cells, which were attributed either to degenerative changes related to vagal overstimulation[63,64,67] or to immaturity.[65,66] On the other hand, Rintoul and Kirkman[68] suggested that Dogiel type I ganglion cells (primarily motor) were selectively absent in IHPS. Belding and Kernohan[64] and Spitz and Kaufmann[69] found that the majority of myenteric ganglion cells in the hypertrophic pylorus showed degenerative changes. However, Tam[70], using immunohistochemical stains for neuron-specific enolase, stated that neurons were neither immature nor severely degenerated. Langer et al.[82] demonstrated using electron microscopy that there were fewer nerve cell bodies in the myenteric plexus in IHPS, and the total number of ganglia was lower than that in control samples.

Cholinergic and adrenergic innervations

Cholinergic nerve distribution has been studied using acetylcholinesterase (AChE) histochemical staining. Strong AChE staining was observed in the myenteric plexus and the muscle layers in controls, whereas in IHPS specimens, AChE staining was markedly decreased in the muscular layers but strong in the myenteric plexus.[74]

The studies from our laboratory have reported that adrenergic immunoreactivity is absent in the muscular

layers and markedly decreased in the myenteric plexus in IHPS in comparison to controls.[5]

Nitrergic innervation

Nitric oxide (NO) is a gaseous free radical, synthesized from L-arginine in a reaction catalyzed by nNOS. NO has a well-described role as a major nonadrenergic, noncholinergic inhibitory neurotransmitter that mediates pyloric relaxation in the enteric nervous system.[83] Vanderwinden et al.[79] and Kobayashi et al.[73] have reported that enzyme NADPH diaphorase, which is identical to NO synthase,[84] is absent or markedly reduced in hypertrophic pyloric muscle, while it is preserved in the myenteric plexus in IHPS. Furthermore, a NOS gene-deleted knockout mouse model is described in which the only abnormality is a constant gastric-outlet obstruction due to pyloric hypertrophy.[85] Barbosa et al.[86] administered nitro-L-arginine methyl ester hydrochloride (L-NAME), a known NOS inhibitor, to pregnant rats and their newborns, and then noted that the L-NAME rats had a larger stomach and pyloric hypertrophy. Kusafuka and Puri[40] demonstrated low levels of nNOS mRNA in pyloric muscle of IHPS patients compared to normal controls. Since a low level of nNOS mRNA may lead to impaired local production of NO, it is suggested that the excessively contracted hypertrophied circular muscle in IHPS is a result of reduced expression of the nNOS gene at the mRNA level.[40]

More recent research showed that sphincter tone is determined by the balance between the nNOS-dependent relaxant and the Rho-associated protein kinase 2 (ROCK-2)-dependent contraction effects.[87] nNOS's NO generation potential depends on the coupled dimeric state of the enzyme.[87] When uncoupled, nNOS predominantly generates reactive oxygen species (ROS).[88] It has been shown that ROS generation promotes ROCK-2 activation.[89,90] Welsh et al.[87] have investigated nNOS and ROCK-2 expression in pyloric stenos using a hyperphenylalaninemia-1 (hph-1) newborn mouse model. These mice exhibit transient pyloric smooth muscle hypertrophy, gastric distension, and failure to gain weight that spontaneously resolves with development.[91] The hph-1 mouse has a congenital mutation in the gene coding GTPCH-1, a rate-limiting enzyme in the production of tetrahydrobiopterin (BH4), an essential nNOS cofactor.[91] BH4 deficiency results in nNOS uncoupling, leading to an increase in tissue ROS content and tissue NO deficiency.[92] Welsh et al.[87] have demonstrated that the hph-1 pyloric tissue nNOS downregulation is a secondary phenomenon and not primarily related to the gastric stasis. Both a reduction in nNOS-derived NO and ROS-induced ROCK-2 upregulation account for the newborn hph-1 mice increases in the pyloric sphincter muscle tone. The mechanism accounting for the age-dependent pyloric changes in hph-1 mice is unclear but likely related to the degree of nNOS uncoupling and tissue BH4 content. It is unclear whether BH4 deficiency plays a role in the IHPS pathogenesis. However, breast milk, as opposed to infant formulas, has a high BH4 content, and IHPS rarely occurs in infants that are exclusively breastfed.[87,93]

Synapse formation

Synapses provide the final neuronal control of the GI tract by regulating neurotransmission at the neuromuscular terminals. The reduction of synaptic vesicles and presynaptic terminals in hypertrophied pyloric muscle layers has been demonstrated.[71,77] Furthermore, a study from our laboratory reported markedly reduced neural-cell adhesion molecule (NCAM) expression on nerve fibers within circular and longitudinal muscles in patients with IHPS compared with normal pylorus.[73] NCAM plays an important role in the formation of initial contacts between nerve and muscle cells and affects tissue formation during embryogenesis.[94,95] These reports suggest that there is impairment of neurotransmission between nerves and muscle in IHPS.

Nerve-supporting cells

The nerve-supporting cells (NSCs) permit cell bodies and processes of neurons to be ordered and maintained in a proper spatial arrangement, and are essential in the maintenance of basic physiological functions of neurons.[96] The NSCs of the intrinsic enteric nervous system are often referred to as enteric glia.[5] Enteric glia have been reported to express various markers for both astrocytes and Schwann cells, such as glial fibrillary acidic protein (GFAP), a specific marker for astrocytes within the central nervous system, and S-100,[97] a marker for astrocytes and Schwann cells. A study from our laboratory demonstrated that in IHPS cases, S-100 and GFAP-immunoreactive fibers were either absent or markedly reduced within the hypertrophied circular and longitudinal muscles.[72] The absence or marked reduction of NSC in IHPS corresponds to the absence or reduction of peptidergic, nitrergic, cholinergic, and adrenergic nerve fibers, and is additional evidence that a defect of intramuscular innervation exists in IHPS.

ABNORMALITIES OF THE INTESTINAL PACEMAKER SYSTEM (ICC)

ICC are small fusiform or stellate cells with prominent nuclei and varicose processes that form networks in the GI tissues. They express C-KIT, a transmembrane protein kinase receptor, essential for their development and maintenance. Morphologic studies have suggested three major functions of ICC: (1) they are pacemaker cells in GI smooth muscle[97]; (2) they facilitate active propagation of electrical events; and (3) they mediate neurotransmission.[98,99] A number of investigators have reported a lack of ICC in hypertrophic pyloric muscle from patients with IHPS using C-KIT antibody and electron microscopy.[100,101] The lack of ICC in IHPS suggests the disruption of their network, and the interruption of the generation of slow waves may contribute to the motility disturbances of the pyloric sphincter.[100]

Carbon monoxide (CO) acts as a neurotransmitter in the GI tract and has been shown to cause smooth muscle relaxation. The main source of endogenous CO is through

degradation of heme, catalyzed by heme oxygenase (HO). Heme-oxygenase-2 (HO-2), an isoform of HO, is present in the enteric neurons and in intramuscular ICC, suggesting that CO may serve as an intercellular messenger between enteric neurons, ICC, and smooth muscle cells (SMCs).[102] Our laboratory has investigated immunocolocalization of HO-2 and ICC in IHPS and reported that although intramuscular ICC were HO-2 positive in controls, HO-2 and ICC were not detected in IHPS. It is suggested that impaired intercellular communication between ICC and SMCs may contribute to motility dysfunction in infants with IHPS.[103]

ABNORMALITIES OF ECM PROTEINS

Previous studies have reported an increase in connective tissue in IHPS, particularly in the septa that run between the circular muscle bundles.[63,64] ECM proteins, particularly collagen, are important microenvironmental factors of the neuronal processing pathway in the early embryonal stage and an important matrix for cell adhesion and movement.[5] Cass and Zhang[104] reported an increase in ECM proteins such as chondroitin sulfate, fibronectin, and laminin in specimens of pyloric muscle in IHPS. Another study reported abnormal amounts of elastin fibers and elastin in the pyloric muscle in IHPS.[105] Using M-57 antibody, which can distinguish newly synthesized type I procollagen from fully processed mature collagen, it was reported that type I procollagen was markedly increased in not only the connective tissue septa between circular muscle bundles but also among the circular muscle fibers in patients with IHPS, suggesting that the hypertrophied circular muscle in IHPS is actively synthesizing collagen.[105,106] These studies suggested that increased ECM proteins may be responsible for the characteristic "firm" nature of the pyloric tumor.

Desmin is the main protein of intermediate filaments and is important for the organization and function of muscle fibers. A strong expression of desmin was observed in pyloric muscle biopsies from infants with IHPS, in contrast to absent or weak expression in tached controls. A similar pattern of strong desmin expression has been demonstrated in the fetal pylorus, suggesting that the organization of intermediate filaments in IHPS is in a fetal state of development.[107]

ABNORMALITIES OF SMCS

The ongoing contractile tone in the smooth muscle sphincters is generated by myogenic mechanisms. Langer et al.[82] found SMCs in IHPS to be morphologically normal, containing contractile filaments, intermediate filaments, dense bodies, and caveolae. They found, however, that SMCs in IHPS were frequently in a proliferative phase, with large amounts of dilated rough ER with a lower proportion of contractile filaments, and very few gap junctions exhibited between SMCs compared with control specimens. In contrast, they demonstrated significant ultrastructural abnormalities of the inhibitory enteric nervous system in IHPS. We performed quantitative evaluation of proliferative activity in pyloric muscle in IHPS and showed that proliferative activity is markedly increased in SMCs in IHPS.[108]

Gentile et al.[109] studied cytoskeletal elements of pyloric SMCs in IHPS using immunohistochemical staining and confocal laser microscopy. Talin, a protein responsible for SMC–ECM interaction, and dystrophin, a protein with adhesion properties, were present in controls but absent in IHPS patients, suggesting that the membrane-cytoskeleton interactions and the cell-matrix communications are altered.

Romeo et al.[110] investigated dystroglycans and sarcoglycans, two proteins that, along with dystrophin, form the dystrophin–glycoprotein complex, which is important for maintaining the structural integrity and function of muscle fibers. They reported that although dystroglycans showed similar expressions in IHPS and controls, sarcoglycans were present in controls but absent in IHPS. It is suggested that lack of sarcoglycans can alter the physiology of SMCs and predispose to IHPS.

ABNORMALITIES OF GROWTH FACTORS

Growth factors are peptides that control cell proliferation and modulate cellular functions by binding to specific high-affinity cell membrane receptors. Although the mechanisms responsible for smooth muscle hypertrophy are unknown, with progress in molecular biology, there is increasing evidence to suggest that the growth of SMCs is regulated by several growth factors.[111–113] IGF-I and PDGF-BB are potent SMC mitogens in vitro and act synergistically to stimulate SMC proliferation. IGF-I mediates the growth-promoting effects of PDGF in mesenchymal cells.[114] IGF-I and PDGF have been shown to be produced by SMCs, and their effects are mediated via their receptors.[115,116] Transforming growth factor alpha (TGF-α) is a growth regulatory peptide found in a wide range of embryonic and adult tissues. It has been recognized that TGF-α has a growth-promoting effect on vascular and visceral SMCs.[117] Epidermal growth factor (EGF) is best known as a potent growth stimulator. It appears to play a critical role early in growth of cultured smooth muscle, in which its production is highest and its growth-promoting effects are greatest.[117] The studies from our laboratory have reported increased expression of IGF-I, PDGF-BB, TGF, and EGF, in hypertrophic pyloric muscle in IHPS,[5,118–120] suggesting that the increased local synthesis of peptide growth factors in SMCs may play a critical role in the development of pyloric muscle hypertrophy in IHPS.

PATHOLOGY

In IHPS, the mean appearance of the pylorus is that of an enlarged muscle mass usually measuring 2 to 2.5 cm in length and 1 to 1.5 cm in diameter. On histological examination, marked muscle hypertrophy and hypoplasia[108] primarily involving the circular layer and hypertrophy of the

underlying mucosa are described.[121] Increased fibroblast, fibronectin, proteoglycan chondroitin sulfate, desmin, elastin, and collagen have been found on the immunohistochemical analysis of the hypertrophic muscle.[104,105] Abnormally contorted and thickened nerve fibers have been shown with confocal microscopy.[122] These changes are causing either partial or complete obstruction of the pyloric canal.

CLINICAL FEATURES

The usual onset of symptoms occurs between 3 and 6 weeks of age; however, it can present earlier.[123] Demian et al.[124] investigated 278 patients with IHPS, and only 16 (5.8%) were presented during the first 14 days of life. Presentation of HPS in infants older than 12 weeks of age is considered rare, and reports in the literature are few and far between.[125,126]

Vomiting is the most common presenting symptom. Initially, there is only regurgitation of feeds, but soon it is characteristically projectile and free of bile. In 17%–18% of cases, the vomitus may contain fresh or altered blood, usually attributed to irritative gastritis or esophagitis.[127] Persistent vomiting in these patients results in gastric hydrogen ion loss and subsequent hypochloremic, hypokalemic, metabolic alkalosis.[128]

Owing to inadequate fluid and calorie intake, dehydration and weight loss soon become apparent. In patients who present late, there is disappearance of subcutaneous fat and wrinkled skin. Stools become infrequent, dry, firm, and scanty. However, some infants have diarrhea (starvation diarrhea).

Jaundice occurs in about 2% of cases and has been shown to be related to decrease in glucuronyl transferase, which occurs as a consequence of starvation.[129]

Pylorospasm and gastroesophageal reflux give similar clinical findings, and it may be difficult to differentiate them from IHPS without further evaluation. Other surgical causes of nonbilious vomiting include gastric volvulus, antral web, periampullary duodenal stenosis, duplication cyst of the antropyloric lesion, and ectopic pancreatic tissue within an antropyloric muscle, which are all far less common than IHPS. Common medical causes of nonbilious vomiting are gastroenteritis, increased intracranial pressure, and metabolic disorders (Table 52.1).[34]

Associated anomalies are found in 6%–20% of patients.[130,131] These include esophageal atresia, malrotation of bowel, Hirschsprung's disease, anorectal anomalies, cleft lip and palate, and urological anomalies.

Table 52.1 Differential diagnosis of IHPS

Surgical conditions	Medical conditions
Gastric volvulus	Pylorospasm
Antral web	Gastroesophageal reflux
Periampullary duodenal stenosis	Gastroenteritis
Duplication cyst	Increased intracranial pressure
Ectopic pancreas within the pyloric muscle	Metabolic disease

DIAGNOSIS

It should be possible to diagnose HPS on clinical features alone in 80%–90% of infants.[132–134] The important diagnostic features of pyloric stenosis are visible gastric peristalsis and a palpable pyloric tumor. Physical examination of the infant is best carried out during a test feed, which relaxes the abdominal wall and makes the detection of pyloric tumor easier. The abdomen is completely exposed and observation made for gastric peristalsis, which is often visible in this condition as a bulge appearing in the left upper quadrant and moving slowly to the right across the epigastrium. On palpation of the abdomen, an olive-shaped pyloric tumor is palpable in most cases just above the umbilicus at the lateral border of the rectus muscle below the liver edge. However, Bakal et al.[135] have shown that the frequency of development of an olive-shaped abdominal mass evident on physical examination decreased significantly over time. Early diagnosis triggers timely support and surgical intervention, and thus may prevent development of a classical clinical and laboratory findings of late-stage IHPS. The remarkable recent advances in ultrasonographic devices and techniques allow IHPS to be diagnosed earlier than formerly.[135,136]

The diagnosis by ultrasonography relies on the measurement of the pyloric diameter, pyloric length, and muscle thickness, and the hypertrophied pylorus often looks obvious at first glance: "the hot dog in a bun" appearance.[137] Of the three parameters, muscular wall thickness is considered to be the most precise on sonography. Blumhagen and Coombs[138] were the first to point out that pyloric muscle thickness of the hypoechoic ring is the most important sonographic parameter in the diagnosis of pyloric stenosis (Figure 52.1). They considered a thickness of 4 mm or more to be pathological. Other investigators believe that muscle thickness of 5 mm or more is most reliable for the diagnosis

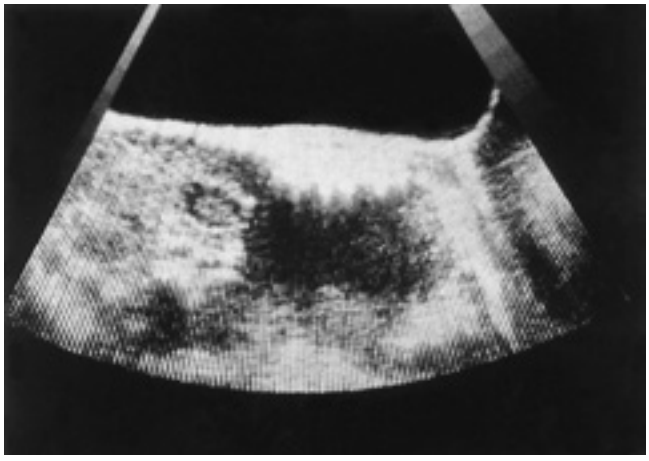

Figure 52.1 Longitudinal real-time sonogram section reveals hypoechoic ring with echogenic center typical of pyloric tumor.

Figure 52.2 Pyloric stenosis. Severe narrowing of pyloric region giving the "string sign" in this 3-week-old infant who presented with projectile vomiting.

of pyloric stenosis.[139] False-positive results are rare, but false-negative rates range from 0% to 19% and largely depend upon the skill of the ultrasonographer.[131,139] In recent years, ultrasound has been used by surgeons to diagnose pyloric stenosis and leaving only problematic or equivocal cases for the radiologist. With this method, IHPS is diagnosed immediately from the emergency room, decreasing hospital stay.[13]

Barium meal study is still a highly sensitive examination for the diagnosis of IHPS. In patients in whom the pyloric tumor cannot be palpated and ultrasound is not definitive, usually it confirms the diagnosis and it may also detect gastroesophageal reflux or intestinal malrotation. Before barium study, the stomach should be emptied with a nasogastric tube and 30–60 mL of barium is instilled under fluoroscopic control. The characteristic radiological feature of pyloric stenosis is a narrowed elongated pyloric canal giving a "string" or "double track" sign caused by compressed invaginated folds of mucosa in the pyloric canal (Figure 52.2). However, barium meal study provides indirect information about the antropyloric canal status. Failure of the relaxation of the antropyloric lesion, known as pylorospasm, demonstrates the same findings as those of IHPS. The emptying speed of the barium meal to the distal bowel will be important to differentiate these two conditions.[140]

MANAGEMENT

Preoperative management

Estimation of serum electrolyte level, urea nitrogen level, hematocrit, and blood gases should be done to determine the state of dehydration and acid–base abnormalities. We have to keep in mind that severe metabolic alkalosis has a potential effect on central control of ventilation and respiratory drive.[141] However, several studies have shown that the classic electrolyte abnormalities of hypochloremic, hypokalemic, metabolic alkalosis are present in less than half of the patients with IHPS.[142,143] Some studies have suggested that the prevalance of electrolyte derangement in IHPS may have diminished in the past three decades.[143,144] More recent study from Tutay et al.[128] have shown that most patients with IHPS demonstrated no alkalosis and no electrolyte derangement. They suggested that this is caused by earlier diagnosis given and consequent earlier correction of dehydration and electrolytes. Anesthesia can be safely performed when serum chloride is >100 mEq/L and the serum HCO3- is <30 mEq/L.[141]

If the babies with IHPS do not show any clinical evidence of dehydration on admission, their serum electrolyte levels are usually normal. They are given their maintenance requirements of fluid as half-straight saline and are operated on as soon as feasible. If the infant is mildly dehydrated and has hypochloremic alkalosis, maintenance fluids can be given as 0.45% saline with 5% dextrose containing 10 mmol of potassium chloride per 500 mL, together with adequate volumes of isotonic saline to correct for continuing nasogastric losses. If the infant is more severely dehydrated (>5%), sodium and chloride ions must be replaced with isotonic saline to enable the kidney to excrete bicarbonate, thereby correcting the acid–base status.[30,131] The operation for IHPS is not an emergency and should never be undertaken until serum electrolyte levels have returned to normal.

A nasogastric tube is passed to keep the stomach empty. Saline irrigation through the nasogastric tube may help in removing mucus and milk curd. And if the barium meal study has been carried out prior to surgery, it may be necessary to remove the residual barium meal by gastric aspiration.

Operation

The Ramstedt's pyloromyotomy is the universally accepted operation for pyloric stenosis.

INCISION

A 3 cm transverse right upper quadrant incision provides excellent exposure and direct access to the pylorus with minimal retraction (Figure 52.3). Another incision that is commonly used is an umbilical fold incision. This technique achieves an excellent cosmetic outcome with an apparently unscarred abdomen.[145–148]

PROCEDURE

The transverse incision lateral to the rectus muscle is cut through all layers of muscle and peritoneum. The pyloric tumor is delivered by gentle traction on the stomach (Figure 52.4). The surgeon applies an index finger to the duodenal

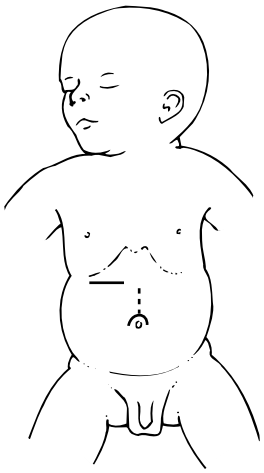

Figure 52.3 Skin incision for pyloromyotomy.

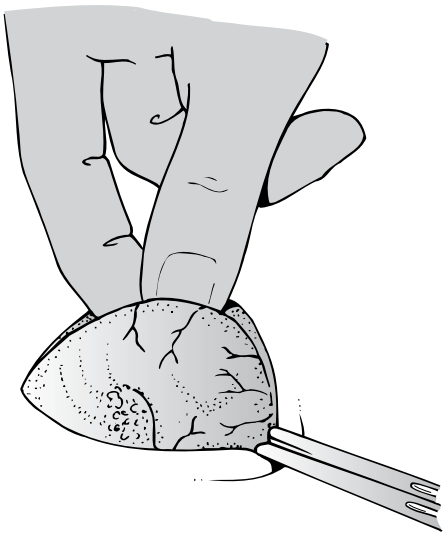

Figure 52.4 Delivery of pyloric tumor.

end of the pylorus and stabilizes the pyloric tumor. An incision is then made over the anterosuperior part of the pylorus, beginning at the clearly demarcated pyloroduodenal junction about 2 mm proximal to the pyloric vein and extending onto the gastric antrum, where muscle is thin (Figure 52.5). The pyloric muscle is then widely split down to the mucosa using mosquito forceps (Figure 52.6). Some surgeons prefer a Denis Browne pyloric spreader. When the pyloric muscle has been adequately split, the mucosa can be seen to be bulging (Figure 52.7). If mucosal injury is questionable, to test the injury, the stomach is inflated through the nasogastric tube and passage of air through the pylorus to duodenum is confirmed. Then the pylorus is dropped back into the abdomen. The peritoneum is closed with 4-0 polyglactin (Vicryl) and muscles approximated using 3-0 polyglactin (Vicryl). 5-0 Vicryl is used for subcuticular stitches.

Tan and Bianchi described the supraumbilical fold approach for pyloromyotomy. Circumumbilical incision is made through about two-thirds of the circumference of the

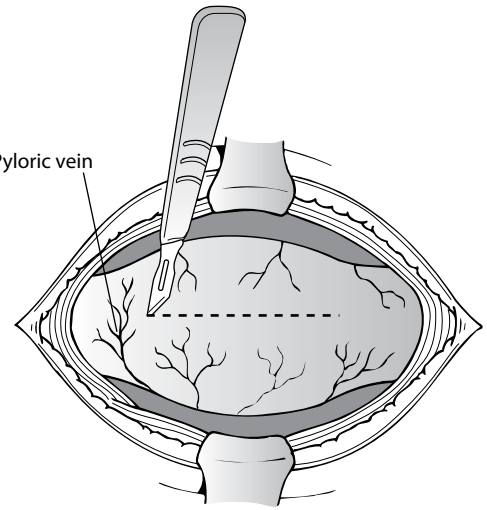

Figure 52.5 Incision through the serosa of the pyloric tumor.

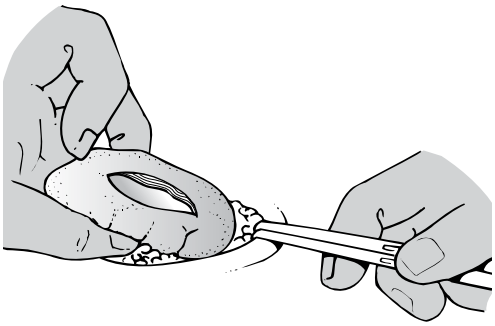

Figure 52.7 Bulging mucosa seen after complete splitting of pyloric muscle.

umbilicus. The skin is undermined in a cephalad direction above the umbilical ring, and linea alba is exposed. The linea alba is divided longitudinally in the midline from the umbilical ring to as far cephalad as necessary to allow easy delivery of the pyloric tumor.[145–148] The problem with the supraumbilical incision is that it does not always allow easy access to the hypertrophic pyloric muscle. Delivery of a large pyloric tumor can be fairly difficult and time-consuming, and may damage the serosa of the stomach or duodenum by tearing.[145]

LAPAROSCOPIC PYLOROMYOTOMY

Since 1991,[149] when the first laparoscopic pyloromyotomy was reported, there have been numerous publications supporting this approach,[140,150] and recently, single incision laparoscopic pyloromyotomy also has been reported.[151] For the laparoscopic procedure, the patient is placed in the supine position at the end of the table. A 5 mm port is placed in the umbilical fold after an open technique under direct vision. Pneumoperitoneum is established with CO_2 at maximum pressure of 6–8 mmHg. Two additional access sites are placed in the left and right midclavicular line just below the costal margin under direct vision with the camera. The duodenum is grasped with atraumatic forceps just distal to the pylorus olive and stabilizes it. Endotome or diathermy hook is placed through the right incision, and the pylorus is incised in its avascular plane from the prepyloric vein well into the gastric antrum (Figure 52.8). The muscular layer is then separated with an endoscopic spreader (Figure 52.9). A satisfactory pyloromyotomy is evidenced by ballooning of the intact mucosa. The absence of mucosal perforation is checked by insufflations of air in the nasogastric tube; if none is seen, the instruments and ports are removed. The umbilical fascia is closed with 4-0 absorbable suture, and the skin of all the wound is reapproximated with 5-0 subcuticular absorbable sutures.[34]

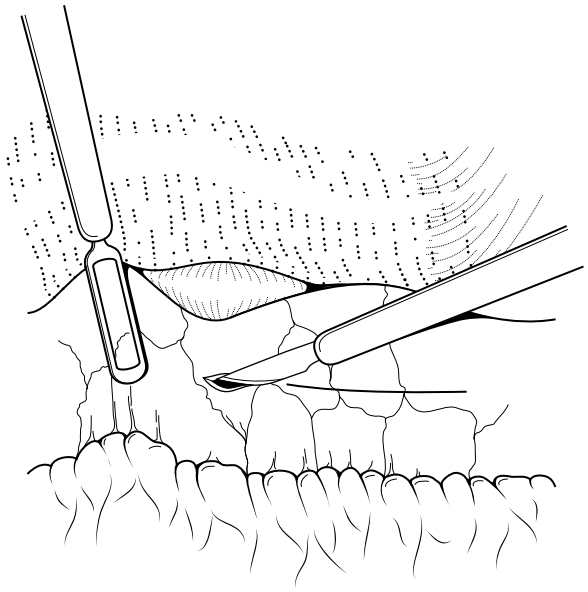

Figure 52.8 Laparoscopic incision.

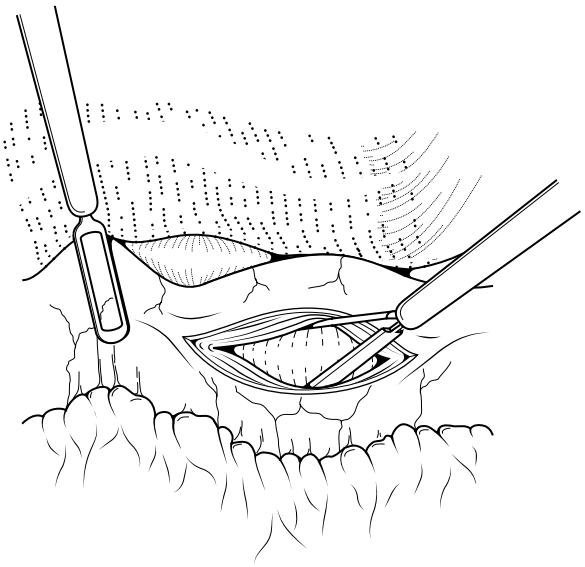

Figure 52.9 Muscular layer is separated with an endoscopic spreader.

Compared to open pyloromyotomy, laparoscopic pyloromyotomy is associated with significantly shorter postoperative recovery, decreased analgesia requirements, and superior cosmetic result in prospective, randomized controlled trials.[152–155] However, this is not much cosmetic advantage when compared with the umbilical approach. Moreover, as Hall et al.[156] have shown in their randomized controlled trials, that laparoscopy is associated with significantly higher frequency of incomplete pyloromyotomy (1.16% versus 0.29%) and a trend of higher perforation rates with laparoscopy (0.83% versus 0.29%).[157] A recent systematic review[158] has concluded that if the surgeon is able to perform both procedures, it is at the discretion of the surgeon or the center to make a well-founded decision between the two options.

Postoperative care

Maintenance i.v. fluids are continued postoperatively until the infant is feeding satisfactorily. The timing of reintroduction of feeds continues to be controversial.[159–162] Several studies have investigated postoperative feeding regimens for IHPS patients with respect to time of reintroduction of feeding and speed of advancement in an attempt to discover the safest and most cost-effective method. Some practice patterns have initiated feedings as soon as the infant awakens from anesthesia.[163] Some authors have suggested a period of withholding feedings for several hours postoperatively,[164] while others have recommended a significantly longer period of starvation up to 18 h before initiating feedings.[165] The ongoing debate arises over whether a surgeon chooses a standardized, incremental feeding regimen versus an ad libitum feeding schedule that allows the infant to decide when and how much to eat.[166] Many concerns surrounding immediate feeding regimens take into account the degree of postoperative gastroparesis.[166] Studies analyzing

radiographic and manometric functional variables suggest that gastric peristalsis completely ceases for 4–6 h postoperatively and is profoundly depressed for 12–18 h postoperatively.[167] Based on the current literature, an ad libitum feeding regimen may be superior to a variety of scheduled, incremental feeding regimens.[166] A majority of the studies found no increase in the incidence of postoperative emesis despite reaching full strength feeds more quickly, thereby decreasing time to discharge.[161,168,169] Therefore, Graham et al.[166] have recommended in their meta-analysis, based on high evidence, to delay feeds for a period of at least 4 h postoperatively, and then to initiate ad lib feedings.

COMPLICATIONS

Duodenal perforation is usually the result of excessive separation of fibers at the distal end of the pylorus. It is not serious provided that it is recognized and closed with one or two sutures. A patch of omentum should be brought up and tied over the wound.

A mucosal injury has always been a major intraoperative complication, generally occurring in less than 5% of cases.[170] Several different approaches of dealing with mucosal injury have been described: full-thickness closure, rotation of the pylorus, repyloromyotomy in a different quadrant, and simple primary mucosal repair.[170] Waldron et al.[170] have demonstrated in their recent study that most of the mucosal injuries (93%) were noticed intraoperatively. Mucosal injuries that are noticed and addressed intraoperatively resulted in few complications, regardless of the repair method. Primary mucosal repair was equivalent to full-thickness closure in terms of complications and outcomes.

The need for reoperation after pyloromyotomy because of recurrent vomiting is reported with an incidence of up to 1.6%. Other complications included hemorrhage, wound infection, wound dehiscence, and gas embolus. With improvements in techniques, the incidence of complications after pyloromyotomy is very low.

CONSERVATIVE THERAPY

The use of antimuscarinics in IHPS was first reported by Svensgaard in 1935, and until the late 1960s, IHPS was often treated medically using oral atropine sulfate.[171,172] Over the past 20 years, atropine sulfate has been used increasingly in Japan as primary therapy for IHPS.[172] As atropine sulfate is a cardioactive drug, electrocardiographic and pulse-oximetry monitoring is required during administration of the drug.[173] In Western countries, medical management of IHPS has remained a controversial issue: the success rate of medical treatment with atropine is lower (75%–88%) than that of surgery (98%), and it requires longer hospitalization because of intravenous therapy and the need to continue oral atropine after discharge, the latter requiring a lot of parental effort.[174] Additionally, due to the lower success rate, patients whose symptoms do not resolve with atropine therapy may then have to undergo surgery when their health has deteriorated even further.[174] Surgery, on the other hand, carries the usual risks of general anesthesia, a risk of mucosal perforation, wound infection, and adhesions.[174] Mercer and Philips[174] have demonstrated in their meta-analysis that a conservative approach to the treatment of IHPS with atropine sulfate should only be considered as an alternative to surgical pyloromyotomy, where longer hospital stays and a reduced success rate are acceptable. This would apply to patients who are unsuitable or at high risk for surgery, and to areas of the world where surgery on small infants is unsafe.

Gastric volvulus

ALAN E. MORTELL AND BRENDAN R. O'CONNOR

INTRODUCTION

Gastric volvulus is a rare, potentially life-threatening condition first described by Berti in 1866.[1] A review of the world literature in 1980 identified only 51 cases in children under 12 years of age.[2] Of these, 26 (52%) were infants, and half of these were younger than 1 month of age. In a recent series, neonates have accounted for only 21% of cases of gastric volvulus.[3,4] In older children, gastric volvulus may be associated with neurodevelopmental delay and splenic abnormalities, but in neonates, there is a strong link with diaphragmatic defects. In the last three decades, numerous descriptions of acute and chronic gastric volvulus in children have been published, bringing the total number of reported cases to more than 640.[3–8]

ETIOLOGY

Gastric volvulus may be defined as an abnormal rotation of one part of the stomach around another[9]; the degree of twist varies from 180° to 360° and is associated with closed-loop obstruction and the risk of strangulation. Lesser degrees of gastric torsion are probably common, frequently asymptomatic, and not diagnostic of volvulus. Such cases may be associated with transient vomiting in infants, but spontaneous resolution is the rule.[7,10] Gastric volvulus may be either organoaxial, occurring around an axis joining the esophageal hiatus and the pyloroduodenal junction, or mesenteroaxial, around an axis joining the midpoint of the greater and lesser curves of the stomach (Figure 53.1). The majority of patients present with organoaxial volvulus (54%) compared to mesenteroaxial volvulus in 41% and combined volvulus in only approximately 2% of cases.[3] A mixed or combined picture occurs if the stomach rotates around both axes simultaneously. The usual direction of rotation is anterior; i.e., in organoaxial volvulus, the greater curve moves upward and forward above the lesser curve, causing the posterior gastric wall to face anteriorly. The gastroesophageal junction and the pylorus may both become obstructed. In anterior mesenteroaxial rotation, the antrum comes to lie anterosuperior to the fundus, and obstruction is usually in the antropyloric region.

Acute, complete volvulus is most often seen in infancy in contrast to chronic and partial varieties, which more often occur in older children and adults. More complex patterns of gastric volvulus have been described in neonates and infants with abnormal gastric bands or adhesions (see later), and in older children after gastrostomy[11,12] or Nissen fundoplication, performed either open[13–15] or laparoscopically.[16]

CLINICAL CASES

The following three cases illustrate different aspects of the presentation and management of gastric volvulus in infancy.

Case 1

A full-term male infant presented soon after birth with cyanotic attacks during feeding. A tracheoesophageal fistula was initially suspected, but a plain chest radiograph (Figure 53.2a) showed a gastric shadow lying in front of the heart, and a barium swallow (Figure 53.2b) demonstrated an organoaxial gastric volvulus within the chest. Via a left thoracotomy, the stomach was derotated and reduced into the abdomen with repair of the esophageal hiatus. A gastropexy was not performed, and subsequent progress was uneventful.

Case 2

A full-term male infant presented at 4 days of age with intermittent vomiting. This was initially attributed to a urinary infection, but the vomiting continued, and a barium meal showed that there was delayed passage of contrast into the stomach from the esophagus. When the barium was injected via a nasogastric tube, the stomach was seen to lie horizontally and to empty very slowly. At laparotomy, the pylorus was hypertrophied, and the stomach was distended. The gastrocolic omentum was deficient along most of the

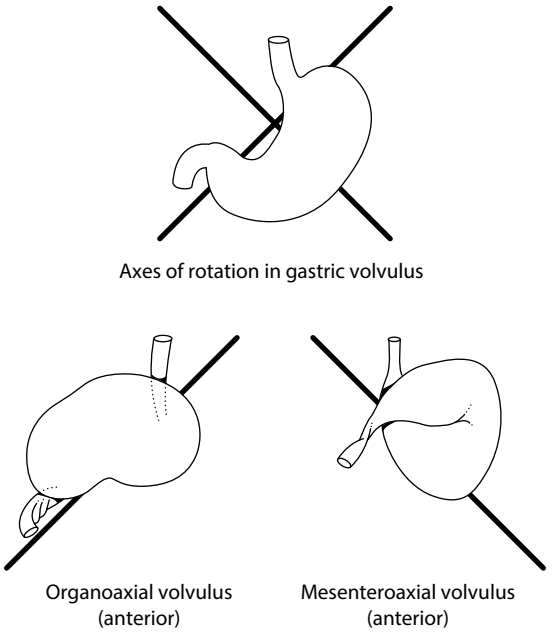

Figure 53.1 Diagrammatic representation of the main types of gastric volvulus.

greater curve, allowing free organoaxial rotation of the stomach. A pyloromyotomy and anterior gastropexy were performed, after which the child became symptom-free.

Case 3

A female infant presented at the age of 2 months with a history of loud borborygmi, inability to bring up wind after feeding, and occasional vomiting. On examination, bowel sounds were heard in the chest. Barium meal showed an organoaxially rotated intrathoracic stomach. Via an abdominal approach, a large paraesophageal hernia was reduced, followed by a crural repair and Nissen fundoplication. The child remained asymptomatic 4 years later.

PATHOGENESIS

The stomach is relatively fixed at the esophageal hiatus and at the pyloroduodenal junction and is also stabilized by four *ligamentous* attachments—the gastrohepatic, gastrosplenic, gastrocolic, and gastrophrenic ligaments (Figure 53.3). Despite these attachments, considerable changes in shape and position of the normal stomach are possible. This is highlighted by the gastric rotation that can sometimes be observed during air insufflation of the stomach at the time of laparoscopically assisted percutaneous endoscopic gastrostomy insertion.[17] Absence or attenuation of the normal anatomical anchors results in abnormal gastric mobility, which may be encouraged still further by a coexistent diaphragmatic defect. Most cases of gastric volvulus in the newborn are secondary to diaphragmatic defects with or without deficient ligamentous attachments.[2,18–24] The contribution of the gastrocolic and gastrosplenic ligaments to

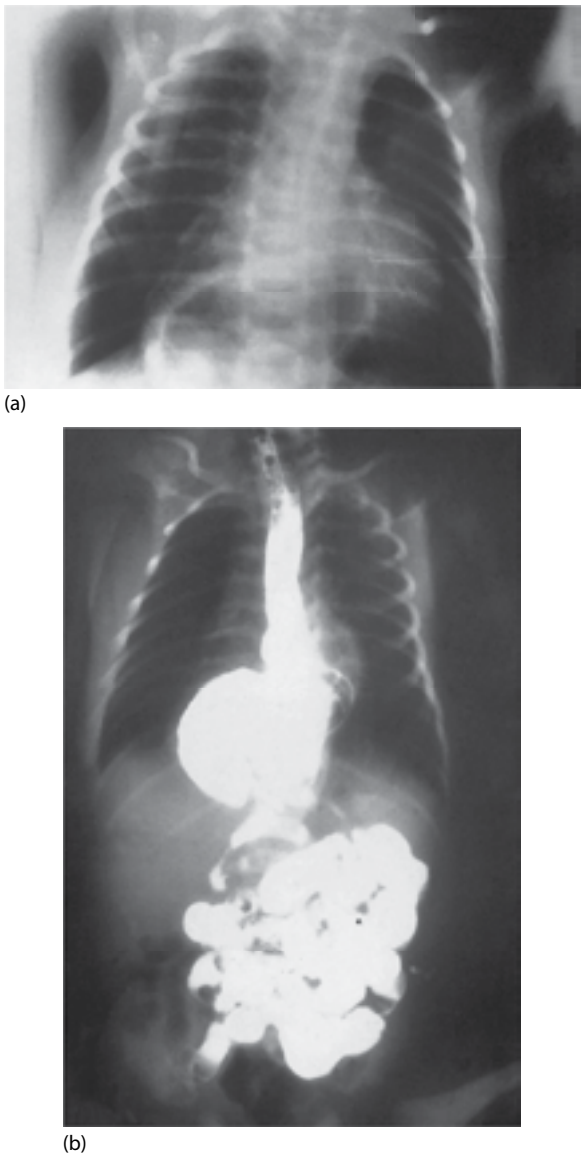

Figure 53.2 **(a)** Plain chest radiograph showing an air-filled viscus in the chest (case 1). **(b)** Barium study showing the stomach lying above the diaphragm with the greater curvature uppermost (case 1).

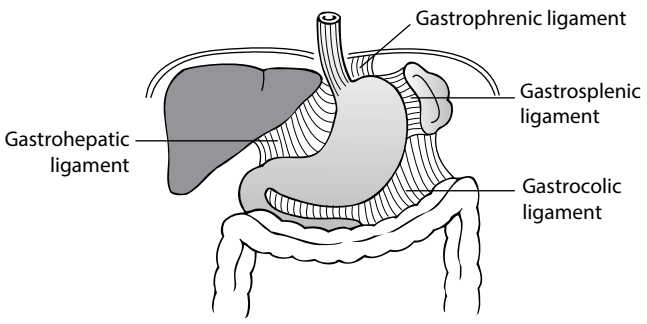

Figure 53.3 Diagrammatic view of the stabilizing gastric ligaments.

fixation of the stomach is demonstrated by the observation in the cadaver that their division allows 180° rotation of the normal stomach.[2,5,25]

Eventration or herniation of the diaphragm is present in about two-thirds of all children presenting with gastric volvulus.[3] However, this proportion is as high as 80% in some series of infants.[2,19] Diaphragmatic hernias are typically paraesophageal or posterolateral defects, but gastric volvulus within a Morgagni hernia is also possible.[3,26] The presumed mechanism of gastric volvulus in this situation is upward displacement of the transverse colon, which pulls up the greater curve of the stomach into the expanded left upper quadrant. Acute gastric volvulus may therefore present as an early complication of diaphragmatic defects.

Gastric distension may encourage the development of gastric volvulus.[25] Infantile hypertrophic pyloric stenosis may rarely be a predisposing factor, as in the second case described earlier. Two similar cases have been reported, but those infants also had diaphragmatic defects.[27,28] Air swallowing can also cause gastric distension, and intermittent gastric volvulus has been reported in an aerophagic neurologically impaired child.[23]

Other rare causes of gastric volvulus in the neonate and infant include the following: abnormal bands or adhesions producing an axis of rotation for the stomach;[6,19,29] rectal atresia with consequent overdistension of the transverse colon;[30] congenital absence or resection of the left lobe of the liver, which may promote abnormal gastric mobility;[31,32] and congenital deficiency of the gastrocolic omentum.[5,33] Asplenic syndrome (asplenia, congenital heart disease, with or without intestinal malrotation and deficiency of the gastric ligaments) is increasingly recognized as a predisposing condition.[34,35] Nakada et al.[36] reported gastric volvulus as a complication in 3 of 25 patients with asplenia, the youngest of whom was 1 month of age. Anchoring gastric ligaments were deficient in all cases. Because of the potentially fatal outcome of acute gastric volvulus in this situation, Okoye et al.[37] have recommended prophylactic gastropexy. Defective fixation and ligamentous laxity also account for the association between gastric volvulus and a wandering spleen.[38–40] Intestinal malrotation is associated with gastric volvulus, even in the absence of asplenia.[6,29,36,41]

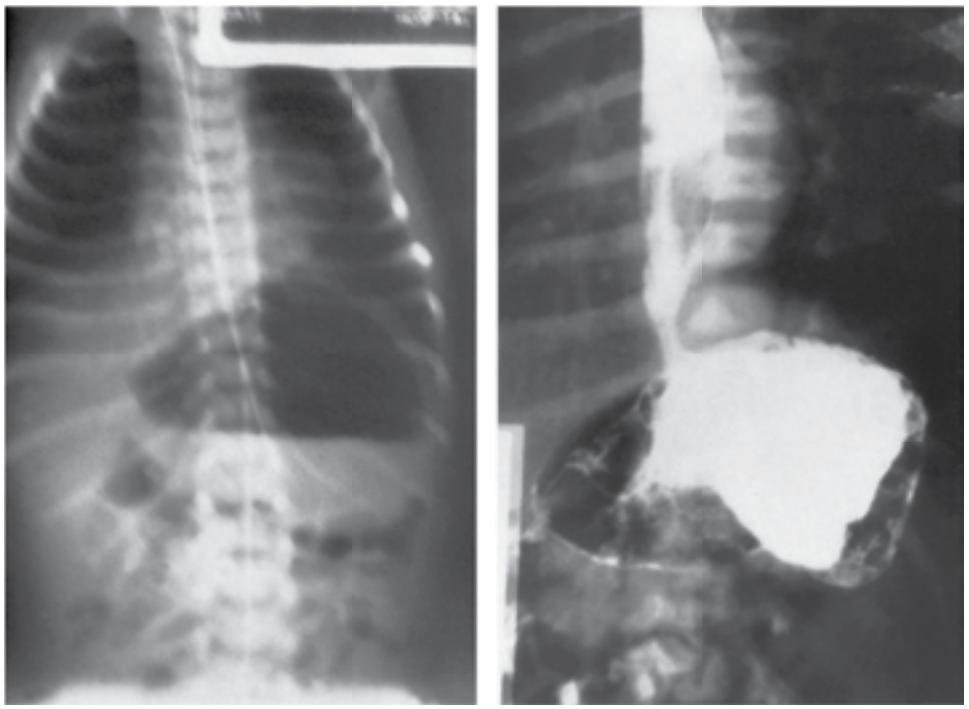
Gastric volvulus in children may rarely arise as a postoperative complication. It has been described after Nissen fundoplication, presumably because the stomach has been extensively mobilized by division of gastrosplenic and gastrocolic attachments.[13,15,16,42] There is one recorded case of gastric volvulus developing after repair of a diaphragmatic hernia[19] and another as an iatrogenic complication of gastric transposition in infancy.[43]

CLINICAL FEATURES

The clinical features depend on the degree of rotation and obstruction. In adults and older children, the Borchardt triad is diagnostic of acute volvulus: (1) unproductive retching, (2) acute localized epigastric distension, and (3) inability to pass a nasogastric tube.[44] These features are difficult to assess in the infant and may be absent. Persistent regurgitation and vomiting (sometimes unproductive) are common, although nonspecific, presenting symptoms in the newborn. The vomitus may or may not contain bile, depending on the degree of pyloric obstruction. Hematemesis and anemia are well described, and occasionally the vomiting is described as projectile. Failure to thrive, chest infections, and less defined respiratory complaints, such as wheeze, are sometimes evident.[41] Upper abdominal pain and distension may be noted in older infants and children. However, abdominal signs may be minimal if the stomach is intrathoracic, when respiratory distress and tachypnea are the dominant features.[2,20,22,45,46] Failure to pass a nasogastric tube may have several causes in the newborn, and the successful passage of a tube does not exclude the diagnosis.[16,19] In neonates, confusion with esophageal atresia is possible, but arrest of the nasogastric tube in the distal esophagus and radiographic abnormalities on routine films should raise suspicion and prompt investigation by contrast studies.[47] In older children, presenting symptoms may be intermittent, chronic, and also nonspecific.[16]

DIAGNOSIS

Plain abdominal and chest radiographs are essential. A distended stomach in an abnormal position should suggest the possibility of gastric volvulus. In mesenteroaxial volvulus, the stomach is spherical on the plain film taken with the patient in the supine position, and two fluid levels are often visible on the erect film—one in the fundus (the lower) and the other in the antrum (upper) (Figure 53.4a); these findings may be absent if the stomach has been decompressed by a nasogastric tube. A paucity of distal bowel gas in acute volvulus can indicate gastric outlet obstruction.[48] Contrast studies clarify the anatomy (Figure 53.4b) and the site(s) of obstruction, which is usually at the pylorus, giving a so-called beak deformity.[18] Organoaxial volvulus is more difficult to diagnose on plain films (especially if there is no associated diaphragmatic defect) and may indeed be missed during a contrast study. The distended stomach lies rather horizontally on the plain film, with a single fluid level. On contrast examination, the esophagogastric junction is lower than normal, the greater and lesser curves are inverted, and the antrum and duodenum are distorted (Figure 53.5). In the presence of a diaphragmatic defect, such as a paraesophageal hernia, the antrum may herniate into the retrocardiac position, producing a fluid level in the chest above the gastric fundus, and thus, organoaxial volvulus can also rarely give rise to two fluid levels.[49] Computed tomography (CT) has been used in cases where gastric volvulus was not diagnosed on plain films; however, it should not be necessary if an upper gastrointestinal contrast study is performed and may only serve to delay treatment.[48] A CT scan can yield further information about structural abnormalities, such as splenic position or absence.



(a) (b)

TREATMENT

Acute gastric volvulus requires appropriate resuscitation and urgent surgery if ischemic necrosis and gastric perforation are to be avoided. If possible, the stomach should be decompressed preoperatively by nasogastric suction, but vigorous attempts to pass a tube must be avoided because of a risk of gastric perforation.[19] An abdominal approach is recommended, even when the stomach lies in the chest, since this allows identification of any associated gastrointestinal anomalies and accurate diaphragmatic repair if required. Occasionally, preliminary needle aspiration of the stomach may be warranted before manipulating a tensely dilated stomach and reducing the volvulus.[50] Any associated diaphragmatic defect should be repaired and the stomach fixed to the anterior abdominal wall (Table 53.1).

Gastrostomy alone may be used for gastric fixation in neonates, since it provides adequate fixation, postoperative decompression, and a route for postoperative feeding. A Stamm gastrostomy using a 10- or 12-French-gauge Malecot catheter secured by a double-purse-string absorbable suture is appropriate (Figure 53.6a). In infants with no predisposing diaphragmatic defect, an anterior gastropexy should be added (Figure 53.6b). This involves suturing the greater curve of the stomach to the parietal peritoneum of the anterior abdominal wall and the undersurface of the diaphragm by a series of nonabsorbable sutures. There are three recorded cases of recurrence following this approach.[51,52] Endoscopically assisted percutaneous anterior gastropexy has also been described as a successful

minimally invasive treatment for chronic mesenteroaxial volvulus in an older child.[53] Fundoplication may be necessary if there is evidence of gross gastroesophageal reflux, but several authors have achieved good results in such cases with a crural repair alone, and a more conservative approach is warranted provided that the tendency to volvulus is prevented.[41,42] Diaphragmatic crural repair must be performed meticulously, as there is often a common hiatus for the esophagus and aorta in these patients.[42] There is no justification for gastrectomy, gastroenterostomy, or the colonic displacement operation described by Tanner[9] in this age group.

In older children with isolated gastric volvulus, preliminary nasogastric decompression followed by a laparoscopic anterior gastropexy is an option,[33,54] and this technique has also been reported in neonates.[55] Laparoscopic management of neonatal intrathoracic gastric volvulus due to a paraesophageal hernia has also been described, consisting of reduction of the stomach into the abdomen with resection of the hernia sac, crural repair, Nissen fundoplication, and gastrostomy.[56] In gastric volvulus due to a wandering spleen, splenopexy alone may be sufficient.[57]

COMPLICATIONS

A number of complications can result from gastric volvulus, including prolonged gastric ileus, pyloric ischemia, gastric outlet obstruction, gastric necrosis, and perforation.[6]

The mortality from gastric volvulus is difficult to assess, with recent series reporting mortality rates of 7.1% in acute gastric volvulus compared to 2.7% in chronic cases.[6] Untreated, gastric volvulus has a mortality rate of up to 80%, highlighting the importance of prompt recognition and treatment. Deaths have been reported due to missed or delayed diagnosis, with subsequent gastric necrosis and perforation, or inadequate gastric fixation.[4,8,19,21,24]

Most recent series report uncomplicated early outcomes after surgery. One long-term follow-up study of nine infants demonstrated no recurrences or late complications.[4]

Gastric perforation

ADAM C. ALDER AND ROBERT K. MINKES

INTRODUCTION

Gastric perforation in the neonatal period is rare; however, it continues to be associated with significant morbidity and mortality. Spontaneous neonatal gastric perforation is estimated to occur in 1 in 2900 live births[1] and accounts for approximately 10%–15% of all gastrointestinal perforations in neonates and children. Gastrointestinal perforations occur more commonly in males; however, there appears to be no sex predilection for those occurring in the stomach.[2] Recent series may suggest a male predominance, but this remains inconclusive.[3] The incidence of gastrointestinal perforation is increasing in some populations; however, the relative incidence of gastric perforation is decreasing.[4] The terminology used to describe neonatal gastric perforation has been inconsistent, and its etiology remains a topic of debate. Spontaneous or idiopathic gastric perforations refer to those with no identifiable underlying cause and account for the majority of gastric perforations in most reported series.[1,5] Nevertheless, many pediatric surgeons believe that an underlying cause can be found in most cases of neonatal gastric perforation.[6]

Siebold, in 1926, is credited with the first description of a gastrointestinal perforation with no demonstrable cause, the so-called spontaneous perforation.[7] In 1929, Stern et al.[8] reported attempts at surgical repair. Agerty et al.[9] reported the first successful repair of a neonatal intestinal (ileum) perforation in 1943, and Leger et al.,[10] in 1950, described the first successful repair of a neonatal gastric perforation. Survival following a neonatal gastric perforation was rare prior to the 1960s. While mortality has improved since that time, it remains significant and ranges from 25% to over 50% in most series.[1]

ETIOLOGY

Gastric perforations in neonates can be broadly categorized as spontaneous (idiopathic), ischemic, or traumatic; however, in many instances, the etiology may be multifactorial. Ischemia, necrosis, and perforation may occur with no obvious inciting factors.[11] Table 54.1 lists several possible causes and associations with gastric perforations. Spontaneous gastric perforations most often occur on the greater curvature.[1] Neonatal gastric perforation can occur in full-term, premature, and small for gestational age neonates. Some infants appear to have been healthy and medically stable prior to the development of the perforation, whereas others have underlying medical conditions or congenital anomalies. There are reports of intrauterine gastric perforation with no known underlying cause.[12] Unrecognized overdistension or ischemic insult may result in a perforation that is thought to be spontaneous. Ischemic perforations occur in the setting of physiologic stress such as prematurity, asphyxia, sepsis, and necrotizing enterocolitis. The perforations are often associated with ulcerations and ischemic tissue. Traumatic perforation results from pneumatic distention during mask ventilation, positive pressure ventilation, or iatrogenic injury during gastric intubation. Several specific causes of neonatal gastric perforation have been reported including intestinal atresias, prenatal stress, trauma, foreign bodies or bezoars, and exposure to corticosteroids and nonsteroidal anti-inflammatory agents (Table 54.1). Several theories on the etiology of spontaneous (idiopathic) gastric perforations have been suggested, but no single theory is universally accepted. Theories include congenital absence of the gastric muscle,[13] forces exerted during vaginal delivery,[14] and pneumatic distention.[15] Studies in dogs and human neonatal cadavers suggest that rupture is caused by overdistention and is in keeping with the law of Laplace.[16] With gastric distention, the greatest wall tension is exerted on the fundus, the site of most spontaneous perforations. In addition, overdistension can cause ischemic changes, a finding present in many cases of perforation.[17]

Recent studies suggest a deficiency of the tyrosine kinase receptor C-KIT^{+} mast cells, and a lack of C-KIT^{+} interstitial cells of Cajal may contribute to idiopathic gastric perforation.[18] Mice lacking C-KIT^{+} mast cells develop spontaneous

Table 54.1 Causes and associations of neonatal gastric perforation

Idiopathic
Perinatal stress
Hypoxia
Asphyxia
Prematurity[19,20]
Anatomic defect
Distal obstruction

Corticosteroids[40]

gastric ulceration or perforation. Pathologic specimens from nonnecrotic portions of the stomach in six spontaneous gastric perforation patients showed a decreased number in interstitial cells of Cajal.[41] In addition, postmortem examination of stomachs of neonates who died of idiopathic gastric perforation revealed a deficiency in both C-KIT$^+$ mast cells and interstitial cells of Cajal when compared to controls. The authors suggest that these abnormalities could result in impaired immunity and abnormal motility predisposing to gastric perforation.[42]

CLINICAL PRESENTATION

The clinical presentation of gastric perforation is variable. The majority of cases present within the first 7 days of life; however, later presentations are reported.[2] The neonates are often premature or have a history of asphyxia or hypoxia.[19] Neonates may present with feeding intolerance or emesis that may contain blood. Many develop abrupt onset of rapidly progressive abdominal distension from pneumo- or hydroperitoneum.[43] These infants progress to respiratory distress, hemodynamic instability, and signs of shock such as hypothermia, cyanosis, poor peripheral perfusion, and low urine output. The abdomen may rapidly become tense and tender with signs of peritoneal irritation. Ventilation may be impaired or ineffective until the abdomen is decompressed. Subcutaneous emphysema in the abdominal wall or pneumoscrotum may be appreciated.[44] Infants with posterior perforations into the lesser sac may present with a more insidious course, making the diagnosis difficult.

Infants with perforation secondary to an underlying process often have evidence of the predisposing condition such as findings of tracheoesophageal fistula, duodenal atresia or web, malrotation, gastroschisis, or diaphragmatic hernia.[19,45] In some instances, a secondary cause is found at the time of operation. In cases of iatrogenic perforation, a history of traumatic naso- or orogastric intubation, prior surgery, corticosteroid or nonsteroidal administration, and aggressive ventilation or cardiopulmonary resuscitation may be obtained.[27]

DIAGNOSIS

The diagnosis of gastric perforation is made from the clinical history, physical examination, and radiographic studies. In infants with massive pneumoperitoneum, a plain abdominal radiograph will demonstrate air under the diaphragm that extends laterally, trapping the abdominal viscera medially and producing a saddlebag appearance.[46] The stomach is not visualized by plain radiograph in 90% of the cases.[47] Other plain radiograph findings include subcutaneous emphysema, pneumoscrotum, ascites, or an oro- or nasogastric tube outside the confines of the stomach. Pneumatosis intestinalis and portal venous air are signs of necrotizing enterocolitis, which may coexist with gastric perforation. Calcification and dilated loops of bowel are common findings of more distal perforation, and a gasless abdomen is seen in cases of neonatal volvulus. A definitive diagnosis may not be made prior to laparotomy. A water-soluble contrast study will reveal extravasation from the stomach into the peritoneal cavity (Figure 54.1). Ultrasound may show ascites or fluid collections. In premature infants with known lung disease, pneumoperitoneum can result from air tracking from the mediastinum. A chest film demonstrating pneumomediastinum, an air-fluid level in the stomach, a negative peritoneal aspirate, and an intraperitoneal drain that bubbles with the ventilator cycle can help to exclude an intra-abdominal process.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis is broad and includes conditions that cause sudden deterioration in the newborn and conditions that produce vomiting and abdominal distention. Conditions causing cardiovascular collapse include sepsis, pneumothorax, cardiac dysfunction, intraventricular hemorrhage, electrolyte abnormalities, hypoglycemia, necrotizing enterocolitis, perforated viscus, and malrotation with midgut volvulus. Conditions associated with vomiting and abdominal distention include Hirschsprung's disease, intestinal atresia, meconium ileus, meconium plug syndrome, imperforate anus, perforated viscus, necrotizing enterocolitis, and midgut volvulus.

(b)

Figure 54.1 Diagnosis. Abdominal distention, pneumoperitoneum seen on these two view films of the abdomen. **(a)** Note the lucency over the liver. **(b)** Pneumoperitoneum becomes much clearer on the lateral decubitus film. There is no evidence of lung disease and no findings suggestive of enterocolitis.

PERIOPERATIVE CARE

Infants with gastric perforation develop septic parameters and need to be resuscitated accordingly. Neonates may become unstable prior to the development of free intra-abdominal air. Infants who develop respiratory distress require intubation, and increased ventilator support is needed as the abdomen becomes more distended. Appropriate laboratory investigations include blood cultures, white blood cell count, hemoglobin, hematocrit, platelet count, electrolyte profile, and blood gas analysis. Broad-spectrum antibiotics should be initiated. Fluid boluses and blood transfusions are given to achieve hemodynamic stability and adequate urine output. An oro- or nasogastric tube should be carefully passed and placed on low intermittent suction. Once free intra-abdominal air is identified, the patient is stabilized and a laparotomy should be performed. Aspiration of the peritoneum with an i.v. cannula when an overly distended abdomen is impeding ventilation can be a lifesaving measure.[20] In select cases, peritoneal drainage has been reported with resolution of the peritonitis and healing of the perforation.[43]

SURGICAL TECHNIQUE

Historically, open exploration and repair is favored. Some reports indicate that gastrointestinal perforations have been found to be spontaneously sealed by adjacent omentum[48] or that pneumoperitoneum, possibly from gastric perforation, can be managed successfully without an operation.[49,50] These case reports often do not have a specific source for the pneumoperitoneum and make use of the non-operative management approach in high-risk patients with successful management of gastric perforation seen as a possible alternative to rather than a replacement for standard operative management. Recently, successful laparoscopic repair of neonatal gastric perforation has been reported.[51] The operative approach should be based on the abilities of the surgeon and local resources.

For an open repair, an upper abdominal transverse skin incision (Figure 54.2) is made and dissection carried through the rectus muscle until the peritoneum is entered. The umbilical vein is divided. The incision can be extended as needed. Peritoneal fluid and debris are evacuated. The abdomen is explored for the site of perforation. When a perforation of the stomach is not found, careful exploration of the gastroesophageal junction, duodenum, small bowel,

Figure 54.2 Incision. Upper abdominal transverse skin incision. The incision can be enlarged to gain access to the entire abdomen.

and colon should be performed. The lesser sac should be opened and inspected for contamination and integrity of the posterior surface of the stomach.

The most common site of a spontaneous perforation is near the greater curvature. The perforation can be small or extensive and extend high on the stomach. For isolated perforations, the devitalized edges of the perforation are debrided back to viable tissue (Figure 54.3). The defect is closed in one or two layers and may be reinforced with an omental patch (Figure 54.4). Stapled closure of a perforation as well as repair around a gastrostomy tube have also been successful. A variety of techniques have been used to manage extensive perforations or necrosis that requires subtotal or total gastrectomy. In a stable infant, subtotal gastrectomy can be performed with reconstruction with an esophagogastric anastomosis.[52] Several techniques for reconstruction after total gastrectomy have been reported including transverse colon interposition, Roux-en-Y esophago-jejunal anastomosis, and Hunt–Lawrence pouch reconstruction.[3] Reconstruction following total gastrectomy in an unstable neonate can be delayed and performed in stages. In the initial surgery, the esophagus is closed and a feeding tube placed distally through the distal gastric remnant or separate jejunostomy. The esophagus is decompressed and the child supported with parenteral nutrition until tube feedings can be initiated through the feeding tube. Reconstruction can be considered several weeks later when the clinical condition and nutritional status have improved.

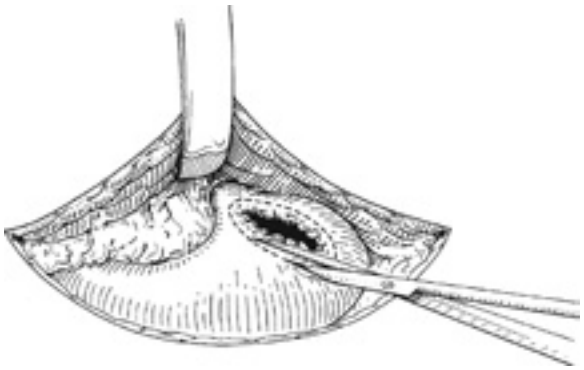

Figure 54.3 Exposure and resection. The entire perforation is exposed. A variable area of the stomach is found to be devitalized or necrotic. The edges of the perforation are resected back to bleeding viable tissue. On rare occasions, extensive resection, subtotal, or total gastrectomy are required.

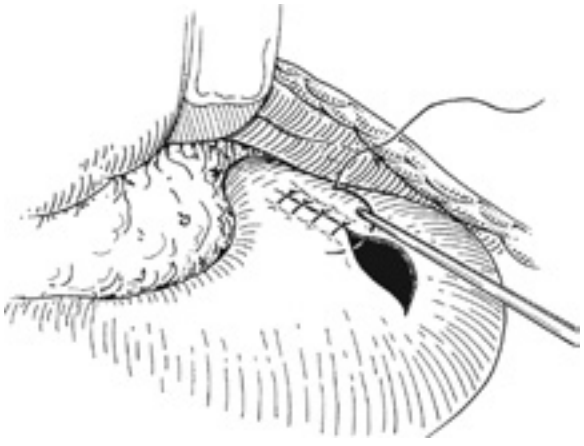

Figure 54.4 Closure. The free edges of healthy tissue are closed in one (depicted) or two layers. An omental patch may be used. Careful inspection of the posterior wall of the stomach and the entire small and large bowel should be performed to exclude additional areas of necrosis.

Following repair of the perforation, the abdomen is lavaged with warm saline. Peritoneal drainage is not needed for most primary repairs and has not been shown to reduce postoperative complications, but are used routinely by some surgeons. The fascia and skin are closed in standard fashions. Postoperatively, supportive and resuscitative care is continued. The child is maintained on broad spectrum antibiotics, gastric acid suppression therapy, and total parenteral nutrition (TPN). The stomach should be decompressed. Feedings are held until the infant has stabilized. Many surgeons obtain a contrast study prior to initiating enteral feeds.

Poor outcomes after gastric perforation have been associated with several clinical factors. Yang et al.[45] found that leukocytosis at admission and thrombocytopenia at 48 hours were associated with poor outcomes. Additional factors predictive of poor outcome include sepsis, metabolic acidosis, and hyponatremia.[45,53] A prompt response to identification of the perforation and appropriate supportive care for the newborn is important for the best clinical outcomes.

CONCLUSION

Gastric perforation in the newborn is a rare event, but with early recognition, appropriate care and adherence to principles of surgical management survival can be maximized. Causes of gastric perforation may be multiple including idiopathic and spontaneous perforation. Recognition of the patterns of symptoms related to gastric perforation will aid in identification of this rare clinical condition. Careful attention to preoperative preparation will aid in a successful repair. Operative principles include control of spill of the luminal contents, debridement of devitalized tissue, and closure of the defect. Postoperative care includes supportive measures, broad spectrum antibiotics, and gastric acid suppression. Nutrition plays a key role in healing with TPN until the stomach is healed. Contrast study of the stomach may be considered prior to initiation of intestinal feeds.

FUTURE DIRECTIONS

Gastric perforation remains a poorly understood and rare event in the neonatal period. Associated risk factors are poorly characterized, and future investigation may help define which patients are at the highest risk. These patients may benefit from gastric acid suppression or other trophic factors to support the stomach. Gastric perforation may be in the same spectrum as necrotizing enterocolitis or

spontaneous intestinal perforation. Investigation related to improved understanding of those processes may provide improvement in the understanding of gastric perforation.

Previous studies have shown the relationship of the C-KIT+ mast cells and the interstitial cell of Cajal to gastric perforation. These underlying cellular and molecular deficiencies are poorly characterized and may represent future targets for therapy or possible preventive strategies.

Finally, technology has assisted in the development of minimal access techniques and minimal access instrumentation. Future instrumentation may be even smaller, and this micro access approach may allow even more technically complex procedures in the neonate. Advancements also allow endoscopic procedures in the neonate, which have been limited up to this point by the size of the endoscope and the available instrumentation. In humans and animal models, gastric perforation has been successfully approached using endoscopic clips[54] and suturing techniques.[55]

Duodenal obstruction

YECHIEL SWEED AND ALON YULEVICH

INTRODUCTION

Congenital duodenal obstruction (DO) is the most common cause of intestinal obstruction in the newborn period, occurring in 1 per 5000–10,000 live births.[1,2] DO is the result of intrinsic lesion, extrinsic lesion, or a combination of both.

These pathological lesions can cause complete or incomplete obstruction. Intrinsic DO may be caused by duodenal atresia, stenosis, diaphragm, a perforated diaphragm, or a "wind-sock" web. The wind-sock web is a duodenal membrane that is ballooned distally as a result of peristalsis from above. Extrinsic DO may be caused by annular pancreas, malrotation, or preduodenal portal vein. Although the annular pancreas forms a constricting ring around the second part of the duodenum (Figure 55.1), it is not believed to be the cause of DO,[3] and there is usually an associated atresia or stenosis in patients with an annular pancreas. Similarly, preduodenal portal vein has also seldom been reported to be the cause of DO, and it is often associated with other causes of intestinal obstruction such as malrotation or duodenal atresia.[4]

Duodenal atresias have been traditionally classified by Gray and Skandalakis[5] into three types (Figure 55.2). Type I defect, the most common (Figure 55.2a), is represented by a mucosal and submucosal diaphragmatic membrane with an intact muscle wall. The opening of the bile duct at the ampulla of Vater is almost always located proximal to the duodenal web. Type II defect has a short fibrous cord that connects the two atretic ends of the duodenum (Figure 55.2b); in type III defect, there is complete separation of the atretic ends with a mesenteric defect (Figure 55.2c). The reported prevalence of type I is about 92%, type II is 1%, and type III is 7%. Duodenal stenosis is approximately half as prevalent as atresia.[6]

Figure 55.3 shows the wide spectrum of various types of DO. The proximal and distal segments of the duodenum may be separated by a gap (Figure 55.3a), be in apposition (Figure 55.3b), or be joined by a fibrous cord (Figure 55.3c). Other types include duodenal stenosis (Figure 55.3d), complete diaphragm (Figure 55.3e), perforated diaphragm (Figure 55.3f), wind-sock web (Figure 55.3g), and annular pancreas (Figure 55.3h).

ETIOLOGY

The underlying cause of duodenal atresia remains unknown, although its pathophysiology has been well described. Frequent association of duodenal atresia or stenosis with other neonatal malformations suggests that both anomalies are due to a developmental error in the early period of gestation. Duodenal atresia differs from other atresias of the small and large bowel, which are isolated anomalies caused by mesenteric vascular accidents during later stages of development. This theory of vascular disturbance was presented by the classic study of Lauw and Barnard.[7]

No predisposing maternal risk factors are known. Although up to one-third of patients with duodenal atresia have Down syndrome (trisomy 21), it is not an independent risk factor for developing duodenal atresia. In the large California population-based registry of 2.5 million infants, the risk of duodenal atresia was found to be 265 times higher in infants with Down syndrome than in those without it, and the corresponding frequencies were 46 and 0.12 per 1000 births.[8]

Although DO is usually not regarded as a familial condition, there have been several reports of familial cases[9] and a very rare group of hereditary multiple intestinal atresias with fatal outcome.[10]

PATHOPHYSIOLOGY

Duodenal atresia, web, and stenosis usually occur in the second part of the duodenum, close to the area of intense embryological activity involved with the development of the biliary and pancreatic structures. These anomalies are believed to result from a developmental error during early fetal life.[11]

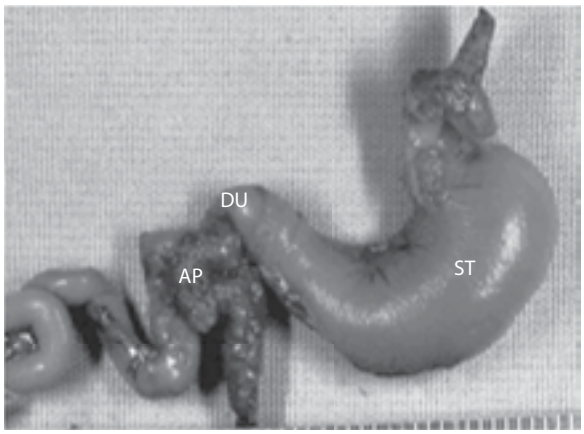

Figure 55.1 Duodenal obstruction caused by an annular pancreas associated with duodenal stenosis in a postmortem of a 14-week-old fetus with a diagnosis of Down syndrome. AP—annular, DU—duodenum, ST—stomach pancreas. (Courtesy of Prof. Bronshtein Moshe.)

Duodenal maldevelopment occurs secondary to either inadequate endodermal proliferation (gut elongation outpaces proliferation), which occurs at 5 weeks of embryonic life, or failure of the epithelial solid cord to recanalize (failure of vacuolization), which appears at 11 weeks of gestation.

Many investigators have demonstrated that the epithelium of the duodenum proliferates during 30–60 days' gestation, completely plugging the duodenal lumen. A subsequent process termed vacuolation occurs whereby the solid duodenum is recanalized. Vacuolation is believed to occur by way of apoptosis, or programmed cell death, which happens during normal development within the lumen of the duodenum. Occasionally, duodenal atresias are associated with annular pancreas. This is likely due to failure of duodenal development rather than robust and/or abnormal growth of the pancreatic buds.[12]

At the cellular level, the gastrointestinal tract develops from the embryonic gut, which is composed of an epithelium derived from endoderm, surrounded by cells of mesodermal origin. Cell signaling between these two embryonic layers appears to play a critical role in coordinating patterning and organogenesis of the duodenum. Sonic hedgehog genes encode members of the hedgehog family of cell signals. Both are expressed in gut endoderm, whereas target genes are expressed in discrete layers in the mesoderm. Mice with genetically altered sonic hedgehog signaling display duodenal stenosis, suggesting that genetic defects in the sonic hedgehog family of genes may influence the development of duodenal abnormalities.[13]

Recently, fibroblast growth factor 10 was found to be active in the duodenum at a late stage of development, and serves as a regulator in normal duodenal development. Fibroblast growth factor 10 (–/–) mutant mice demonstrated duodenal atresia with variable phenotype similar to clinical findings in humans. The phenotype occurred in an autosomal-recessive pattern with incomplete penetrance (38%).[14]

Markljung et al.[9] reported recently on a new familial case of annular pancreas and found one microduplication on chromosome 6q24 by array-based comparative genomic hybridization (CGH) shared by the affected mother and son. This microduplication may be a causative aberration or present a risk factor for the development of annular pancreas and duodenal atresia.

The obstruction of the duodenum usually occurs distal to the ampula of Vater. Preampullary obstruction is much less common, occurring in about 20% of cases. Occasionally, there may be a bifid termination of the bile duct with one limb of the duct system opening into the duodenum above the atresia and one below.[15]

ASSOCIATED MALFORMATIONS

There is a high incidence (approximately 50%) of associated anomalies in patients with intrinsic DO, especially Down syndrome, which occurs in about 30% of these patients.[16,17]

Table 55.1 presents the overall prevalence and distribution of associated anomalies of duodenal atresia. The data are the collected statistics of 1759 patients with DO from a dozen large series.[16] The associated anomalies in order of frequency are as follows: Down syndrome (28%), annular pancreas (23%), congenital heart disease (22.6%), malrotation (20%), esophageal atresia (8.5%), genitourinary malformations (8%), anorectal anomalies (4.4%), and other bowel atresias (3.5%).

Vertebral anomalies were also reported[18] in these patients. Reports of duodenal atresia have also shown a low incidence of associated epidermolysis bullosa.[19]

Other rare anomalies include De Lange syndrome,[18] chromosomal abnormalities,[16] multiple intestinal abnormalities,[19] choledochal cyst,[20] immunodeficiency,[21] and situs inversus.[22]

The complex cardiac anomalies among all other associated malformations are the major cause of morbidity and mortality in patients with duodenal atresia.[2,3,6,23] Dalla Vecchia et al.[6] attributed all the operative mortality (4%) to associated complex congenital heart anomalies in a group of 138 patients with DO in a 25-year survey. Two other important factors affecting higher morbidity and mortality of these patients are prematurity and low birth weight.[3,23,24] The mortality rate is even higher in neonates born with three or more anomalies of the VACTERL (vertebral defects, anal atresia, cardiac defects, tracheo-esophageal fistula, renal anomalies, and limb abnormalities) association, with an overall survival rate of 40%–77%.[25] Spitz and colleagues[26] and, recently, Fragoso et al.[27] reported the combination of esophageal and duodenal atresias as particularly lethal, with mortality rates ranging from 50% to 94%.

PRENATAL DIAGNOSIS/HISTORY

Maternal polyhydramnios has been reported to be present in 17%–75% of cases of duodenal atresia[24,28,29] and is the most common ultrasonographic finding in fetuses with intrinsic DO.[24] Ultrasound is usually performed for suspected fetal or maternal abnormalities when polyhydramnios or a

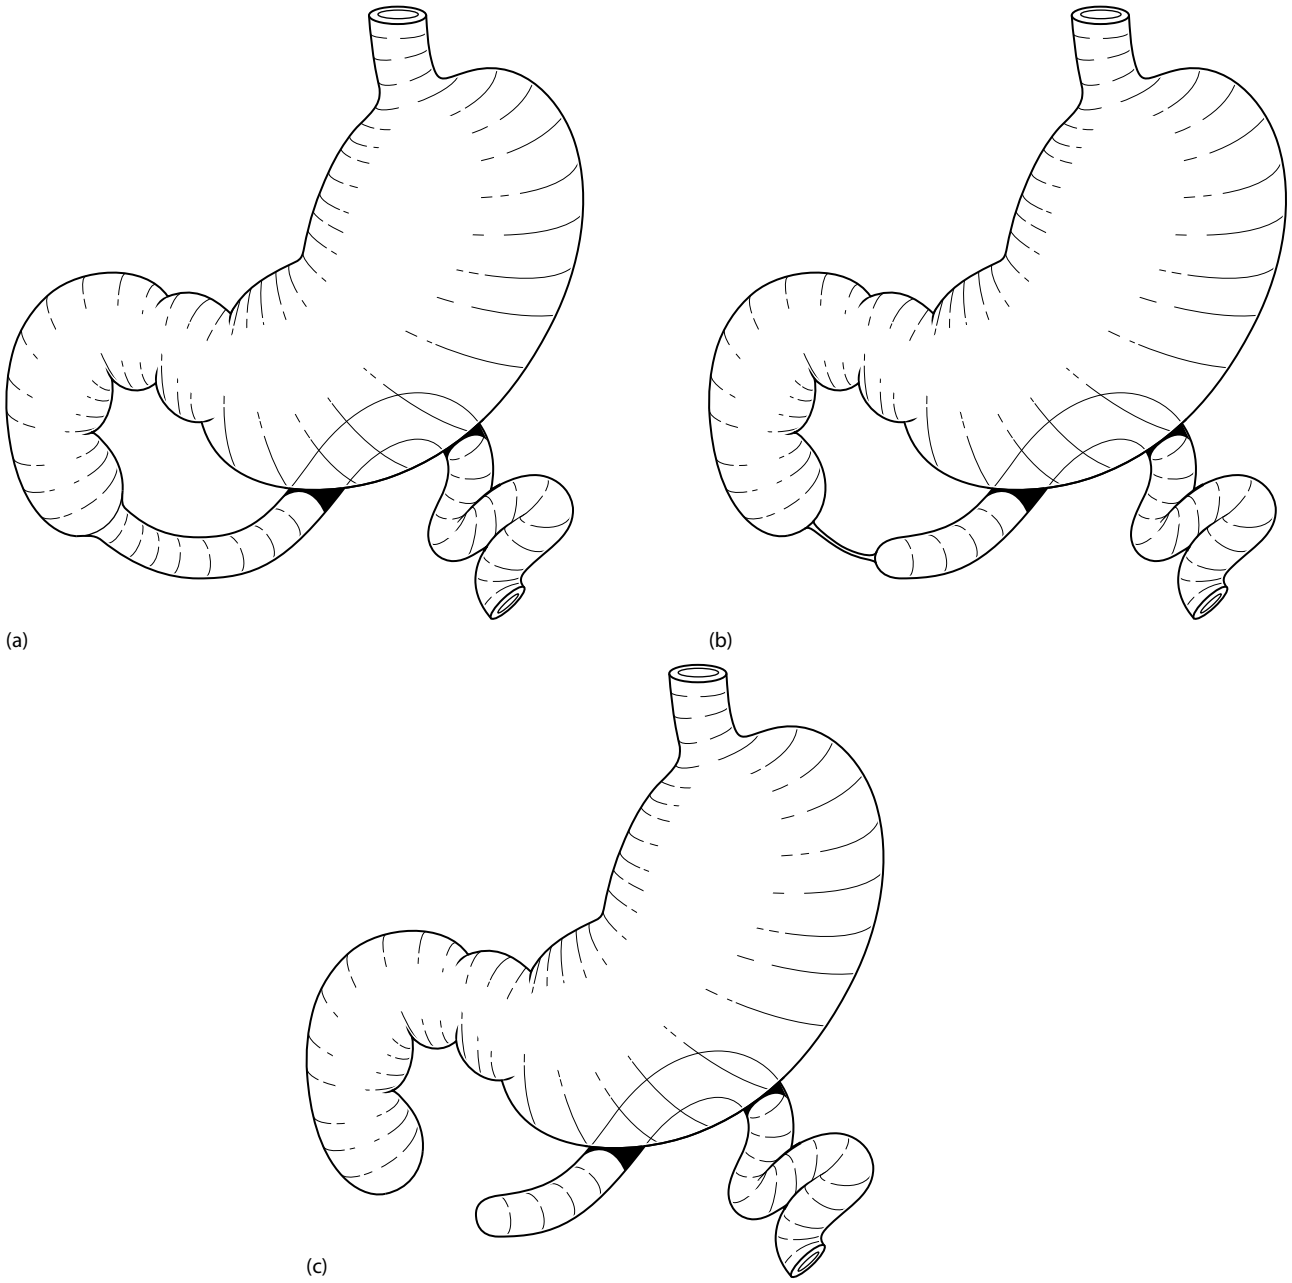

Figure 55.2 Types of duodenal atresia (by Grays and Skandalakis). **(a)** Type I—mucosal membrane with intact muscle wall. **(b)** Type II—fibrous cord connecting the two atretic ends of duodenum. **(c)** Type III—a complete separation of the atretic ends with a mesenteric defect.

large-for-date pregnancy is established. Although the majority of cases are diagnosed during the seventh or eighth month of gestation,[30] sonographic detection of duodenal atresia was reported as early as 12 gestational weeks by Tsukerman et al.[31]

There has been an increase in prenatal ultrasonographic diagnosis of duodenal atresia during the last decades, from 14% between the years 1972 and 1991[32] to a high rate of 57% for the period of 1991–1995.[29]

The prenatal sonographic diagnosis relies on the demonstration of the "double bubble" sign, which is due to simultaneous distension of the stomach and the first part of the duodenum (Figure 55.4). In many cases, this sonographic sign is observed in the second half of pregnancy probably due to hydrostatic pressure needed to dilate the duodenum and also to the degree of the DO.

Visualization of a fluid-filled double bubble (Figure 55.4) on prenatal ultrasound scan is associated with DO secondary to intrinsic lesion, extrinsic lesion, or both. This sonographic finding is known to have a low false-positive rate. Zimmer and Brohnstein[33] have reported that in a few cases, it may represent a transient finding in an otherwise healthy fetus. It is possible that intestinal peristalsis in a fetus may show transient dilatation suggesting DO.[30] On the ultrasound examination, it is also important to demonstrate

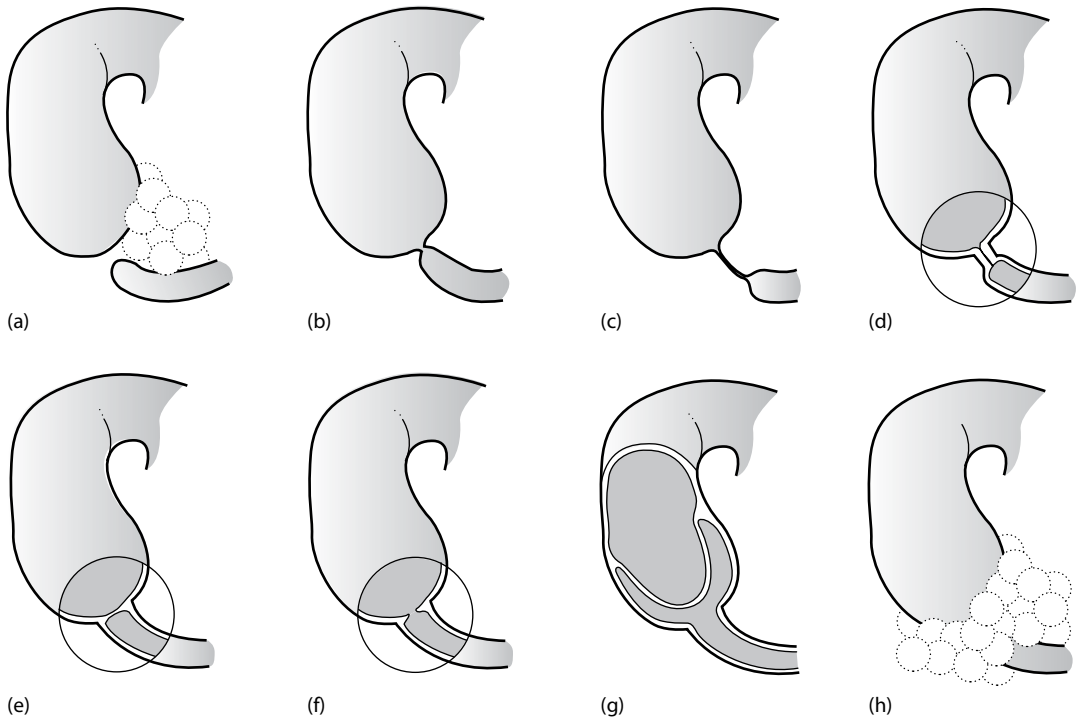

Figure 55.3 Various types of duodenal obstruction. **(a)** Blind ends separated by a gap. **(b)** Two ends in apposition. **(c)** Ends joined by a fibrous cord. **(d)** Duodenal stenosis. **(e)** Complete duodenal membrane. **(f)** Perforated diaphragm. **(g)** "Wind-sock" web. **(h)** Annular pancreas.

Table 55.1 The incidence of associated congenital anomalies (%) (collected statistics) (*N* =1759 patients)

Associated anomaly	%
Down syndrome	28.2
Annular pancreas	23.1
Congenital heart disease	22.6
Malrotation	19.7
Esophageal atresia and tracheo-esophageal fistula	8.5
Genitourinary	8.0
Anorectal	4.4
Other bowel atresia	3.5
Others	10.9

the continuity between the gastric and duodenal bubbles (Figure 55.4) to exclude other causes such as choledochal cyst, which lacks such communication,[34] or duodenal duplication.[35]

Often, other anomalies can also be diagnosed by ultrasound. Pameijer et al.[36] reported on the ultrasonic prenatal diagnosis of a fetus with combined duodenal and esophageal atresias associated with VACTERL anomalies. Prenatal ultrasonographic diagnosis of annular pancreas has also been reported showing the coincidence of the double bubble sign together with hyperechogenic bands around the duodenum (corresponding with the tissue of annular pancreas).[37]

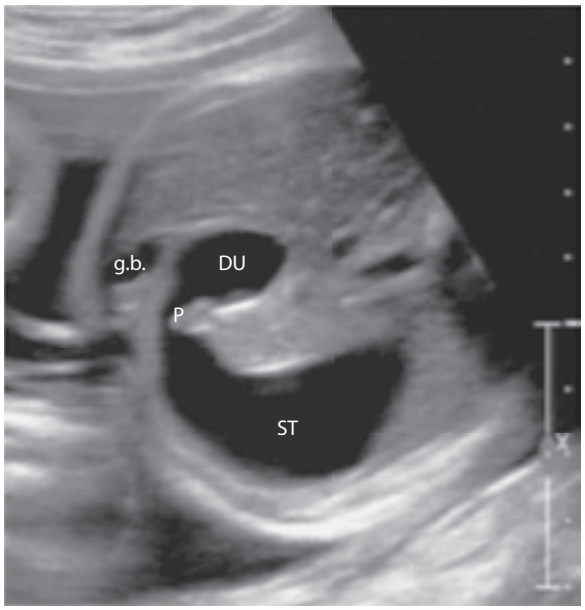

Figure 55.4 Ultrasonography (transverse view) of 24-week-gestational-age fetus showing the "double bubble" sign. DU—duodenum, g.b.—gallblader, P—pylorus, ST—stomach.

Hancock and Wiseman[24] investigated the impact of antenatal diagnosis of congenital DO in a series of 34 infants, 15 of whom were diagnosed by antenatal ultrasound. They concluded that although surgery was performed sooner, the outcome of treatment was not changed by providing an

antenatal diagnosis. However, the antenatal diagnosis of DO influenced parents positively in coping with the anomaly, because it allowed them time to prepare for the medical and surgical interventions required after the birth of their infant. These authors also emphasized that a normal ultrasound in the presence of polyhydramnios does not rule out the diagnosis of DO and is an indication for repeated sonography. Cohen-Overbeek et al.[28] also reported on 91 cases diagnosed with isolated or nonisolated DO. They found that the outcomes of prenatally and postnatally diagnosed DO are not essentially different despite the fact that more prematurity and a lower birth weight were observed in the former.

The rapid advancement in imaging technology, including magnetic resonance imaging (MRI), should allow for diagnosis during the first and early second trimester, enabling abortion.[31] Alternatively, early prenatal diagnosis of DO should lead to karyotype analysis for prenatal screening for trisomy 21 and other associated anomalies.[32,38]

The prenatal diagnosis allows the mother the opportunity to receive counseling and to consider delivery at or near a tertiary care facility that is able to care for infants with gastrointestinal anomalies.[39]

CLINICAL PRESENTATION AND DIAGNOSIS

The presenting symptoms and signs are the result of high intestinal obstruction. About half of these patients are premature and low-birth-weight infants.[3,6,23] Vomiting is the most common symptom and is usually present on the first day of life. Since 80% of the obstructions are located in the postampullary region of the duodenum, vomitus in the majority of cases is bile stained. In supra-ampullary atresia, it is nonbilious. Orogastric aspiration also yields significant volumes of bile-stained gastric fluid. There is minimal or no abdominal distension because of the high level of obstruction. The infant may pass some meconium in the first 24 hours of life, and thereafter, constipation may develop. Dehydration with weight loss and electrolyte imbalance (hypokalemic/hypochloremic metabolic alkalosis) soon follows if the diagnosis is done late and if fluid and electrolyte losses have not been adequately replaced.[40]

Incomplete DO usually leads to the delayed onset of symptoms. Infants with duodenal stenosis and partial bowel obstruction may escape detection of an abnormality soon after birth and may proceed into childhood or, rarely, into adulthood before a partial obstruction is noted.[3,32]

The diagnosis of DO is confirmed on x-ray examination. An abdominal radiograph will show a dilated stomach and duodenum, giving the characteristic appearance of a double bubble sign (the stomach and the proximal duodenum are air-filled) with no gas beyond the duodenum (Figure 55.5a,b,c). In partial DO, a plain film of the abdomen will show a double bubble appearance, but there is usually some air in the distal intestine (Figure 55.6). Occasionally in cases of duodenal atresia, air may be seen distal to the site of obstruction due to associated bile duct bifurcation.[41] Radiographic findings in patients with annular pancreas are usually indistinguishable from duodenal atresia or stenosis.

In some cases of partial DO, plain films may be normal. Upper gastrointestinal tract contrast radiography is indicated in these patients to establish the cause of incomplete DO. This may show a stenotic segment of duodenum with dilatation of the proximal segment, or a sharp termination of the dilated segment, indicating a perforated diaphragm (Figure 55.7).

Incomplete DO usually leads to delayed onset of symptoms, and the diagnosis of duodenal diaphragm with a central aperture is sometimes delayed for months or even years.[42] Mikaelsson et al.[43] reported on the late diagnosis and treatment of 8 out of 16 patients with membranous duodenal stenosis. Their patients were diagnosed and operated at 1 month to 4 years of age. Occasionally, a duodenal diaphragm may be stretched and ballooned distally, giving the wind-sock appearance on a contrast study (Figure 55.8).

The most important differential diagnosis of DO is DO caused by malrotation resulting in extrinsic compression related to Ladd bands across the duodenum, or volvulus of the midgut loop, although this is rare. Midgut volvulus may result in gangrene of the entire midgut within hours, and thus, diagnostic investigation is urgently required, though the symptoms may relent because the obstruction may be incomplete or intermittent in malrotation. Part of these extrinsic obstructions exhibit the double bubble sign with distal air on plain film, while the majority can be identified from the coil spring appearance of small bowel volvulus following barium injection. However, Samuel et al.[44] observed that volvulus neonatorum was not encountered in neonates with duodenal atresia and stenosis who had associated malrotation. They suggested that DO could perhaps be a floodgate that prevents volvulus in these children.

Preduodenal portal vein is a rare anomaly and generally asymptomatic. It is a rare cause of DO and often coexists with other anomalies resulting in bowel obstruction.[4] In most of these patients, it is impossible to diagnose preduodenal portal vein prior to surgery.

The wide variety of additional congenital anomalies, with special emphasis on cardiac malformation, often severe,[23,38] makes preoperative diagnosis imperative. Anterior–posterior and lateral chest and abdominal radiographs ascertaining visualization of the entire spine should also be performed.

Soon after the x-ray, cardiac and renal ultrasound should be carried out routinely in all these babies. A micturating cystourethrogram should be performed in those babies with abnormal urogenital ultrasound or an associated anorectal anomaly. Rectal biopsy should be taken in babies with constipation and the combination of Down syndrome and duodenal atresia, to exclude Hirschsprung disease.[45]

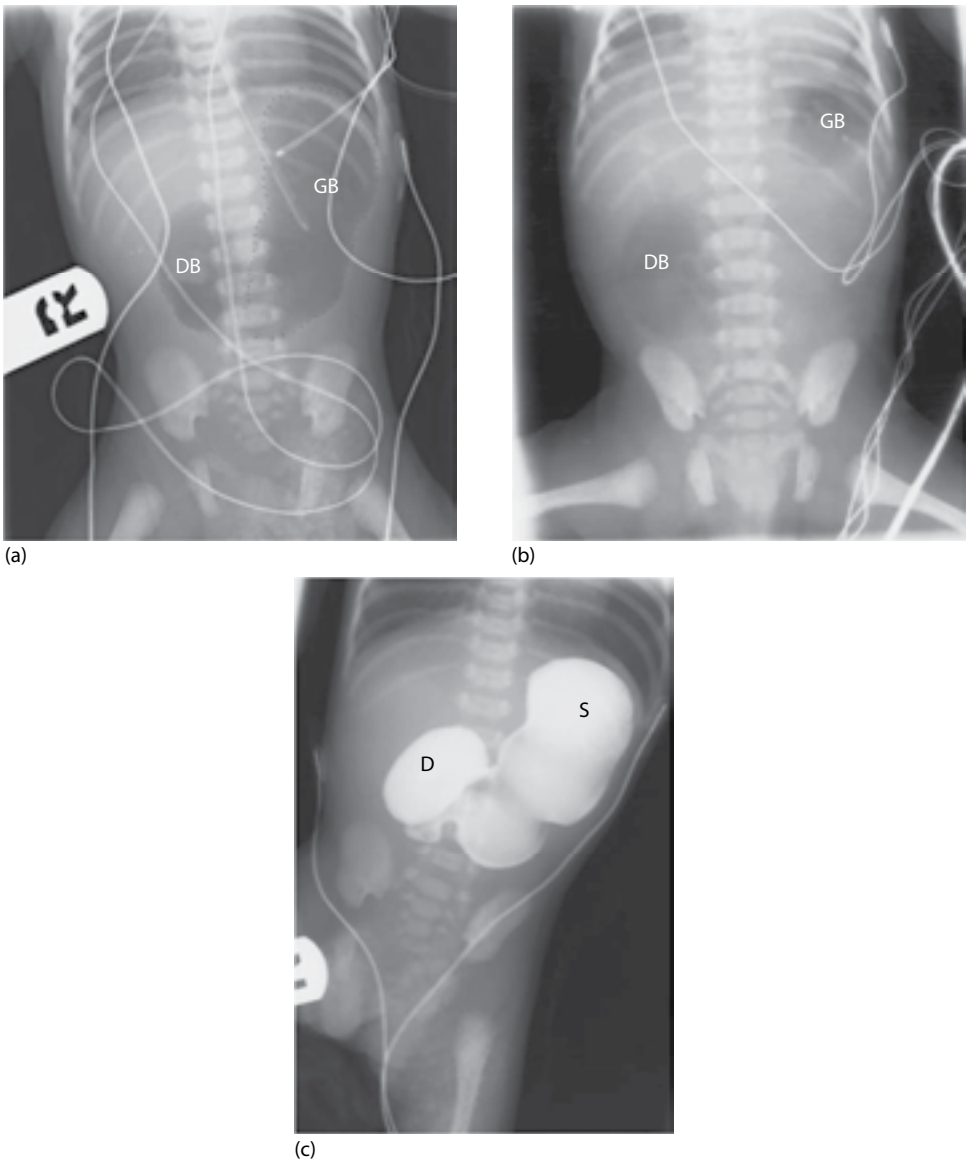

Figure 55.5 **(a)** Abdominal radiograph showing grossly distended stomach and duodenum with "double bubble" sign with no air beyond the duodenum. DB—duodenal bubble, GB—gastric bubble. **(b)** Abdominal radiograph showing the double bubble sign. In this case, the duodenal bulb is more prominent than the gastric bulb. At operation, duodenal membrane was found and excised. DB—duodenal bubble, GB—gastric bubble. **(c)** Duodenal atresia evident on upper gastrointestinal radiograph contrast study. D—duodenum, S—stomach.

PREOPERATIVE MANAGEMENT

Although duodenal atresia is a relative emergency, the patient should not be rushed to the operating room until his/her hemodynamic and fluid and electrolyte status is stable. If the clinical history and findings on physical examination indicate that the baby is in no distress, and the radiographs are consistent with the usual presentation of duodenal atresia with no air beyond the second bubble (excluding malrotation), operation should be performed on an elective basis.

An orogastric tube decompresses the stomach and intravenous fluid resuscitation can be initiated. Blood samples for electrolyte determination should be obtained, and any derangements should be corrected. Prolonged vomiting can result in a hypokalemic hypochloremic metabolic alkalosis. Passage of the orogastric tube rules out esophageal atresia, and careful inspection of anal defect variants of imperforated anus should be performed.

Care is taken to preserve body heat and avoid hypoglycemia, since many of these newborn patients are premature and small for date.[29] Very-low-birth-weight infants or those with respiratory distress syndrome and associated severe anomalies, e.g., congenital heart disease, may occasionally need special preparation such as resuscitation and ventilation.

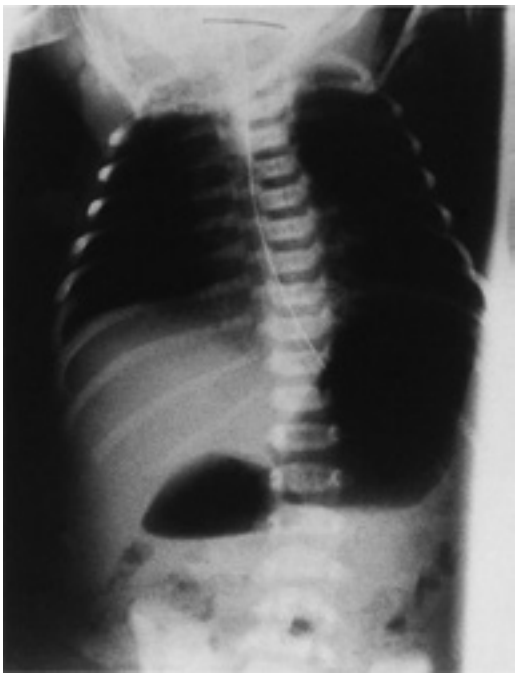

Figure 55.6 Duodenal stenosis erect abdominal x-ray demonstrating a "double bubble" sign with air beyond the duodenum.

OPERATION

Duodenoduodenostomy is the procedure of choice for patients with duodenal atresia, stenosis, and annular pancreas.[6,46]

Duodenoduodenostomy can be performed in either "diamond-shape" (proximal transverse to distal longitudinal) anastomosis as described by Kimura (Figure 55.9a,b)[47] or side-to-side fashion (Figure 55.10). The diamond-shape duodenoduodenostomy has been reported to allow earlier feeding, earlier discharge, and good long-term results.[48]

Bax et al.[49] and Rothenberg[50] reported on the first case and the first series, respectively, on the laparoscopic management of DO. They indicated that the laparoscopic approach has proven to be safe and effective and represents an alternative to the open procedure. They also emphasized that this minimally invasive surgical technique should be used only if the surgeon has appropriate instruments and suturing and laparoscopic skills (Figure 55.11).[49–51]

INCISION

The baby is placed supine on the table with a small roll under his/her upper abdomen on a warming blanket. Endotracheal anesthesia is used. The abdominal skin is prepared by cleaning with prewarmed povidone iodine.

A transverse supraumbilical abdominal incision is made 2 cm above the umbilicus starting in the midline and extending laterally into the right upper quadrant for about 5 cm. The abdominal muscles are divided transversely with cutting diathermy, and the peritoneal cavity is opened in the line of incision.

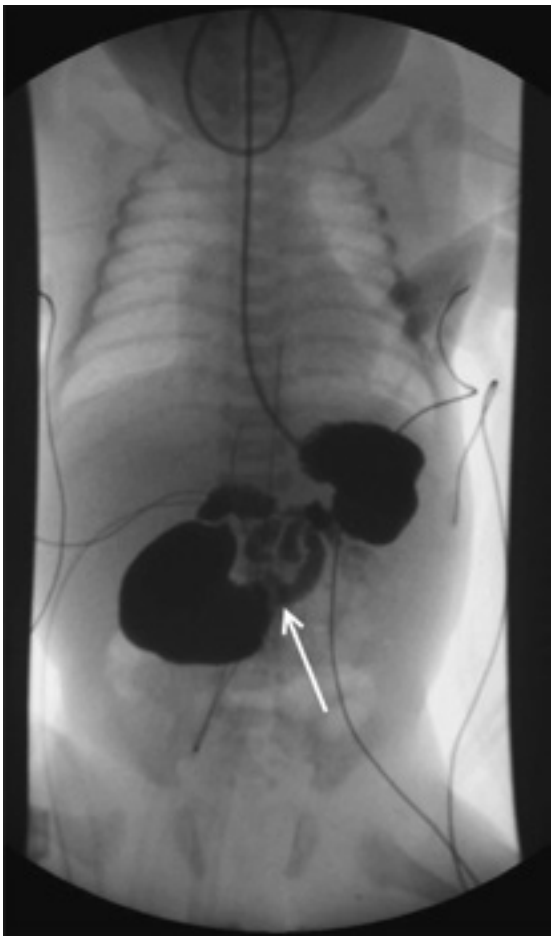

Figure 55.7 An abdominal x-ray contrast study showing marked distention of duodenum terminating abruptly with narrow caliber distally. A perforated diaphragm was found at operation.

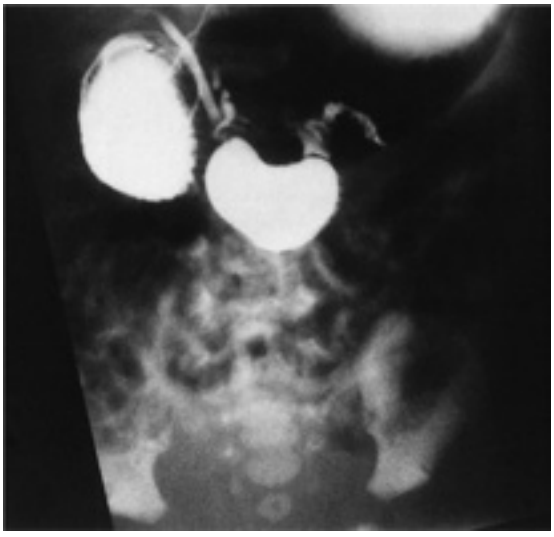

Figure 55.8 "Wind-Sock" web. Dilated duodenum demonstrated with duodenal membrane ballooned distally, giving characteristic "wind-sock" appearance. Reflux of contrast medium into pancreatic and common bile duct is seen.

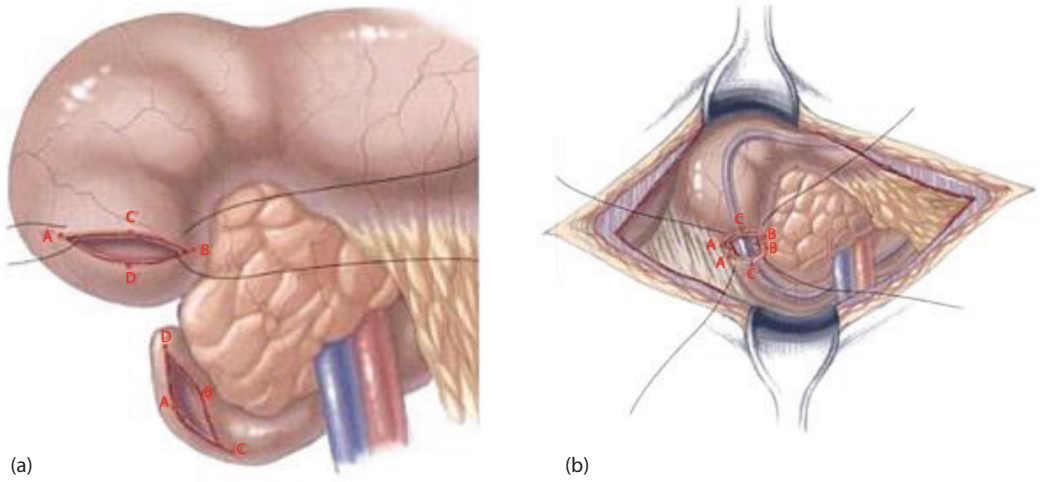

Figure 55.9 Diamond-shaped duodenoduodenostomy. **(a)** A transverse incision is made in the distal end of the proximal dilated duodenum, and a longitudinal incision is made in the smaller limb of the duodenum distal to the occlusion. **(b)** A single-layer anastomosis using interrupted 5-0 Vicryl sutures with posterior knots tied inside the posterior wall of the anastomosis and anterior knots tied outside the anterior wall is performed.

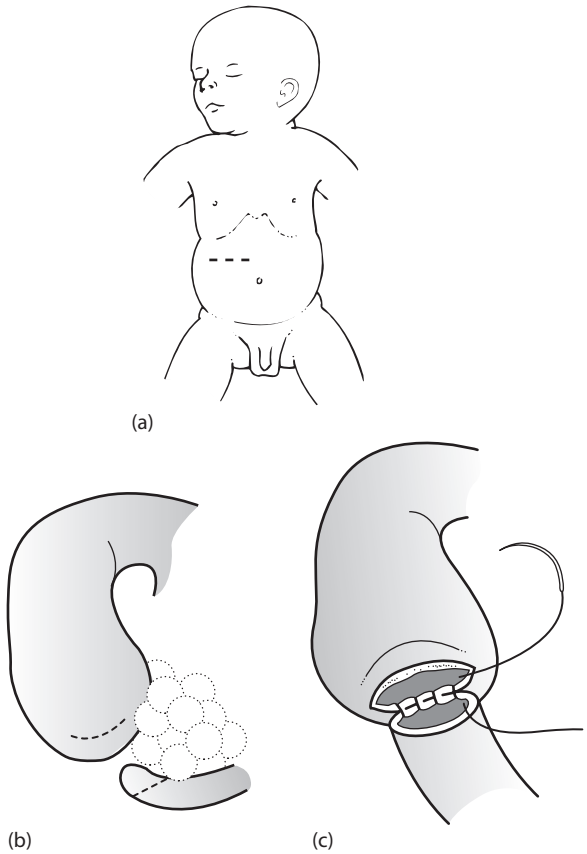

Figure 55.10 Side-to-side duodenoduodenostomy. **(a)** An upper transverse abdominal incision. **(b)** Parallel incisions of about 1 cm are made in the proximal and distal duodenum. **(c)** The anastomosis is preformed using single-layer interrupted 5-0 Vicryl sutures.

EXPLORATION AND IDENTIFICATION OF PATHOLOGY

After exposing the peritoneal cavity, the surgeon inspects the entire bowel for the presence of other bowel anomalies. There may be an associated annular pancreas, malrotation (in about one-third of the patients), or—in rare cases—preduodenal portal vein. If the colon is in normal position, malrotation is probably not a coexisting factor.

The stomach and first portion of the duodenum are usually thickened and dilated. The liver is carefully retracted superiorly. The ascending colon and the hepatic flexure of the colon are mobilized medially and downward to expose the dilated duodenum.[52]

The duodenum is then adequately mobilized and freed from its retroperitoneal attachments—Kocher maneuver. Great care must be exercised not to dissect or manipulate either segment of the duodenum medially, to avoid injury to the ampulla of Vater or the common bile duct. The tube in the stomach is then passed distally into the dilated duodenum and helps to locate the point of obstruction and determine if a wind-sock deformity is present (Figure 55.3g).

The atresia type and any pancreatic abnormality (e.g., annular pancreas) are noted. In patients with an annular pancreas, the pancreatic tissue should never be divided and should always be bypassed. The duodenum distal to the site of obstruction is small and decompressed. The requirements for distal mobilization vary according to the location of the atresia and to the gap between the two segments (Figure 55.2). If necessary, the ligament of Treitz is divided, and mobilization and displacement of the distal duodenum is performed behind the superior mesenteric vessels, thus allowing a satisfactory anastomosis to be performed without any tension.

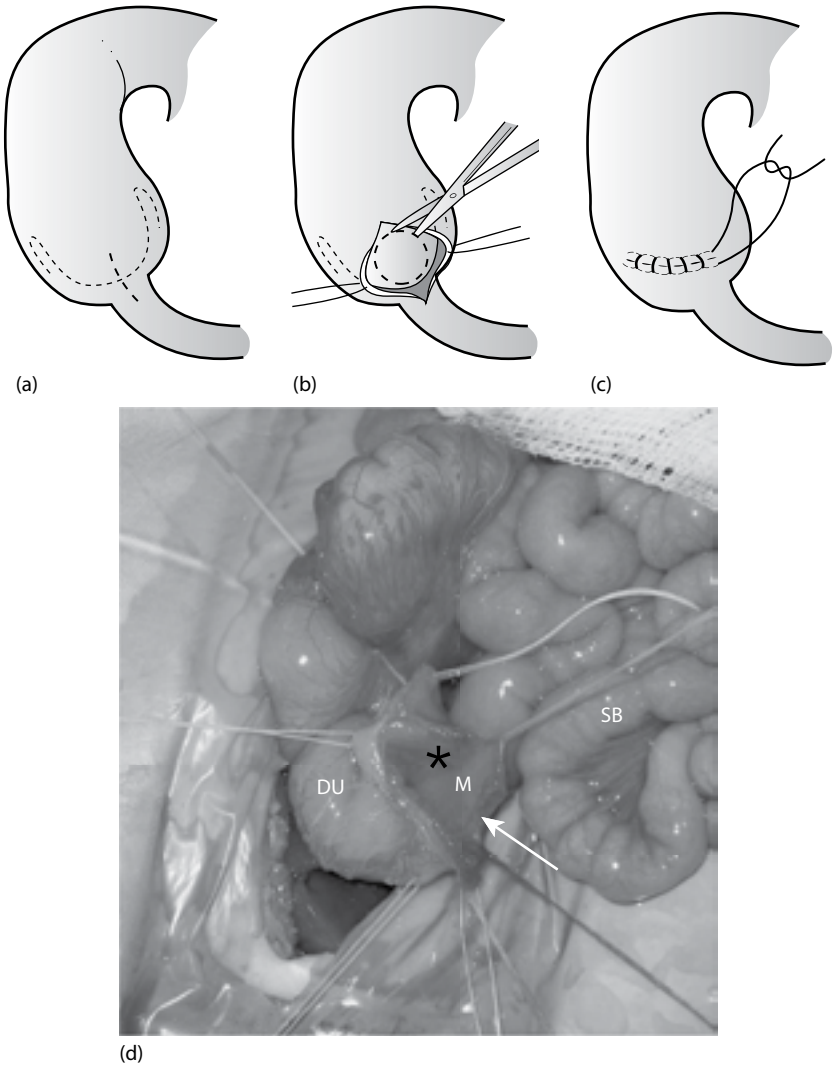

Figure 55.11 **(a–d)** Operative technique for duodenal web. **(a)** Longitudinal incision above the "transitional zone" of the duodenum. **(b)** Excision of the web leaving the medial third of the membrane intact. **(c)** The duodenum is closed transversely. **(d)** Intraoperative photograph of a 2-week-old infant born with duodenal web with an aperture. The papilla of Vater was identified at the proximal and medial part of the duodenal membrane (*). DU, opened duodenum; M, membrane; SB, small bowel; *, papilla of Vater. (*Continued*)

DIAMOND-SHAPED DUODENODUODENOSTOMY

After abdominal exploration, the duodenum is adequately mobilized. With two traction sutures, the redundant wall of the proximal duodenum is pulled downward to overlie the proximal portion of the distal duodenal segment. A transverse incision is made in the distal end of the proximal duodenum, and a longitudinal incision is made in the smaller limb of the duodenum distal to the occlusion.

These are made in such a position as to allow good approximation of the openings without tension.

The papilla of Vater is located by observing bile flow. This is performed by gentle compression of the gallbladder.

The orientation of the sutures in the diamond-shape anastomosis and the overlapping between the proximal transverse incision and the distal longitudinal incision are shown in Figure 55.9a,b.

Additionally, an 8-French Foley catheter should be passed proximally into the stomach and distally into the jejunum and pulled back with the balloon inflated, to ensure that no additional web or wind-sock deformity is overlooked. The distal duodenum can be distended to a larger size during this maneuver, facilitating the anastomosis. Before pulling back the catheter from the distal duodenum, the surgeon should inject 30–40 mL of warm saline through the catheter to rule out distal atresias of the distal small bowel. The catheter is then removed.

A single-layer anastomosis is performed using 5-0 or 6-0 Vicryl sutures with posterior knots tied inside the posterior wall of the anastomosis and interrupted sutures with anterior knots tied outside the anterior wall. Before completion

of the anterior part of the anastomosis, a 5-French silicon nasojejunal transanastomotic feeding tube may be passed down into the upper jejunum for an early postoperative enteral feeding[53] using the same insertion technique as was reported for patients who underwent surgical repair for esophageal atresia and tracheoesophageal fistula.[54] Others, however, do not use the nasojejunal tube, because they suggest that it may delay the commencement of oral feeding.[48] Hall et al.[53] reported recently that a trans anastomotic tube significantly shortens time to full enteral feeds in infants with congenital DO as well as significantly reducing the need for central venous access and parenteral nutrition. Then the right colon is returned to its former position so that the mesocolon covers the anastomosis. The Ladd procedure with inversion appendectomy is performed in patients with malrotation.[32] In these patients, the cecum should be placed in the left lower quadrant to reduce the risk of midgut volvulus.

The wound is closed in layers: the peritoneum and posterior fascia, and the anterior fascia by two layers using continuous 4-0 Vicryl. The skin is closed with running intracuticular suture using 5-0 Vicryl.

SIDE-TO-SIDE DUODENODUODENOSTOMY

The dilated proximal duodenum and the distal collapsed duodenum are approximated using two stay sutures (5-0 Vicryl). Then parallel incisions about 1 cm in length are made in the proximal and distal duodenum (Figure 55.10). An 8-French Foley catheter should be inserted both to the proximal dilated duodenum and to the distal collapsed duodenum in order to rule out wind-sock membrane and distal atresias, as similarly described in the diamond-shape duodenoduodenostomy.

The posterior layer of anastomosis is completed using interrupted 5-0 Vicryl sutures.

At this stage, a transanastomotic 5-French-gauge silastic nasojejunal tube may be inserted for early enteral feeding.

The anastomosis is then completed using interrupted 5-0 Vicryl sutures for the anterior layer. The abdomen is closed in the same manner as described in the diamond-shape duodenoduodenostomy.

In premature infants some surgeons prefer to perform a gastrostomy and insert the transanastomotic silicon tube via the gastrostomy. The tip of the tube should be well down the jejunum so as to decrease the chance of it becoming displaced.

OPERATIVE TECHNIQUE FOR DUODENAL WEB

A longitudinal incision is performed above the "transitional zone" between the wide and narrow segments of the duodenum (Figure 55.11a), and the duodenum is opened. The membrane usually is located in the second part and occasionally in the third portion of the duodenum. It can

be complete or have a hole. Anatomically, the ampulla of Vater may open directly into the medial part of the membrane, or posteriorly close to it; thus, the close relationship of the membrane to papilla of Vater makes its identification mandatory, before excision of the web. Excision of the web should proceed from the lateral duodenal wall, leaving the medial third of the wall intact to avoid damaging the sphincter of Oddi or the ampulla of Vater and continue leaving a circumferential rim of tissue of 1–2 mm (Figure 55.11b,d). The resection line is then oversewn using continuous sutures of Vicryl 5-0, and the duodenum is closed transversely in one layer using Vicryl 5-0 (Figure 55.11c). Because of the pitfalls in cases of the lax membrane that may bulge downward distally into the distended duodenum (the so-called wind-sock phenomenon), and in order to avoid missing the anomaly, before closure of the duodenum, the distal patency of the distal duodenum must be verified by inserting an 8-French Foley catheter through a duodenotomy (Figure 55.11e,f).

The experience with fiber-optic duodenoscopy indicates the usefulness of the technique for both the diagnosis and nonoperative management of duodenal membrane.[55] However, based on reports describing anomalous entry of the pancreatobiliary channels, the delineation of the ducts at endoscopic retrograde cholangiopancreatography (ERCP) may be necessary prior to endoscopic intervention.

Bittencourt et al.[55] reported on three female patients ages 9–12 months born with duodenal membrane who were treated successfully by two endoscopic sessions. The first and second sessions of endoscopic treatment included dilatation and resection of the membrane respectively and were carried out without complications.

Most surgeons, however, believe that a duodenotomy is preferable to the potential risk of inadvertent pancreatic or bile duct injury.

LAPAROSCOPIC MANAGEMENT OF DO

The application of minimally invasive surgical techniques (MIS) for the correction of congenital anomalies has increased significantly over the last 15 years. The ability to perform delicate dissection and intracorporeal anastomosis has broadened the scope of entities that can be approached, including neonatal DO. Although most neonatal conditions presenting with bowel obstruction present a difficult problem for laparoscopy because of the dilated bowel and limited abdominal cavity, this is not the case in duodenal atresia. The entire small and large bowel is decompressed, and there is excellent exposure of the proximal duodenum.[51,56]

For the laparoscopic approach, neonatal laparoscopic instruments (3 mm) and trocars are used. The patient is positioned supine at the end of the operating table, and the surgeon stands at the patient's feet. The abdomen is insufflated through a 5 mm umbilical port, for a 30° laparoscope, and the pneumoperitoneum is established at 6–8 mm Hg (1.5 L/minute). Then two additional trocars are inserted (Figure 55.12a). A 3 mm grasping forceps for lifting the liver can be introduced in the left upper quadrant without a trocar. A better view of the dilated duodenum can be also achieved by using a suture to lift up the falciform ligament. The suture is inserted through the abdominal wall in the right upper quadrant, lifts the ligament, and then is passed back through the abdominal wall and tied.

The first surgical step is to mobilize the colon and the duodenum. A stay suture is inserted through the abdominal wall to move the bulky part of the bulbus duodeni out of the way, allowing a view of the distal duodenum and a more convenient approach to the anastomosis. A transverse incision is made in the distal wall of the dilated duodenum (Figure 55.12b), followed by a longitudinal incision in the distal collapsed duodenum for the diamond-shaped anastomosis of Kimura (Figure 55.12c).

A diamond-shaped anastomosis is performed with either a separate running suture for the posterior and then the anterior wall, or single interrupted stitches of 5-0 Vicryl. Intracorporeal knot tying is used. The distal bowel is examined in all cases to ensure that there are no obvious secondary atresias. Once the anastomosis is completed, the ports are removed, and the sites are closed with absorbable sutures.

When a duodenal membrane is suspected, a longitudinal incision is made on the anterior wall of the duodenum, crossing from the distended duodenum to the distal collapsed duodenum (Figure 55.12d). A urinary catheter is inserted through the abdominal wall directly into the distal duodenal segment, the balloon is filled, and the catheter is gradually pulled back. A membrane with an aperture will stretch itself on top of the balloon. The membrane is incised carefully in its lateral aspect, and the longitudinal incision is closed.

The main benefits of the laparoscopic approach for treatment of duodenal atresia are the excellent visualization of the obstruction and the ease of the anastomosis. However, the possible disadvantage of this approach may be that evaluation of the distal bowel for other atretic segments is more difficult to accomplish, and if not specifically evaluated, it is feasible that a malrotation can be missed.[56] The bowel can be inspected visually for distal obstructed segments, but internal webs may be more difficult to see.

Hill et al.[56] reported recently on their results comparing 22 patients with DO treated by laparoscopy and 36 patients treated by traditional laparotomy during a 9-year period (2001–2010). They found no difference between groups in time to full feeding, postoperative length of stay, and complication rate. They found that the operative time was slightly longer in the laparoscopic group (median time 116 minutes vs. 103 minutes, respectively); however, laparoscopic management appeared to allow a shorter postoperative ventilator requirement. Six patients (26%) of the laparoscopic group were converted to open exploration because of unclear anatomy.

The experience with laparoscopic duodenoduodenostomy[57,58] demonstrates that it can be performed safely and successfully in the neonate with excellent short-term outcomes. Surgeons with experience in advanced laparoscopic techniques can learn laparoscopic duodenoduodenostomy and have good results.

POSTOPERATIVE CARE

The baby is returned to an incubator (or radiant heat cot) at the thermoneutral temperature for its size and maturity. An intravenous infusion of the dextrose/saline is continued in the postoperative period, and further fluid and electrolyte management depends on clinical progress, loss by gastroduodenal aspiration, and serum electrolyte levels. Postoperatively, patients may have a prolonged period of bile-stained aspirate through the nasogastric tube, which is mainly due to the inability of the markedly dilated duodenum to produce effective peristalsis. Enteral feeding through the transanastomotic feeding tube is generally started within 24–48 hours postoperatively.

The commencement of oral feeding depends on the decrease of the gastric aspirate and may be delayed for several days and occasionally for 1–2 weeks or longer. Once the volume of the gastric aspirate decreases, the feeding tube is withdrawn, and the infant can be started on oral feeding.

Spigland and Yazbeck,[59] in their follow-up of 33 neonates, found that bowel transit was established for an average of 13.1 days, 7.5 days after partial web excision, 12.4 days following duodenoduodenostomy, and 15 days after duodenojejunostomy (which is rarely performed today). Spilde et al.[57] reported that the time to initial feeding was 11.3 days for patients with an open repair of DO compared to 5.4 days for those who were treated by laparoscopic approach. They also found that the average time to full oral intake was 16.9 days for the open group compared to 9 days for the laparoscopic group.

Parmentier et al.[60] reported recently that a laparoscopic approach for DO is safe and reproducible with outcomes similar to open repair even in the beginning of a learning curve for pediatric surgeons with appropriate laparoscopic skills. In their small series, laparoscopy did not appear to decrease time to full oral intake or length of stay.

MANAGEMENT OF PERSISTENT MEGADUODENUM BY DUODENOPLASTY

The deformity and dysfunction of the first part of the duodenum—the megaduodenum—are the well-known causes of morbidity,[61] and occasionally, these patients require duodenoplasty. The malfunction of the greatly dilated gut and the absence of effective peristalsis occur in the dilated duodenum proximal to the duodenal atresia. Several techniques of duodenoplasty have been described, and in all, it is of the utmost importance to visualize and identify the ampulla of Vater within the duodenal lumen prior to resection and tapering of the duodenum. Hutton and Thomas [61] have reported success by extensive tapering duodenoplasty. Adzick et al.[62] and Grosfeld and Rescorla[32] emphasized the merit of tapering duodenoplasty at the primary operation of neonates with dilated duodenum, to

improve the immediate postoperative gastrointestinal function and the prevention of further development of megaduodenum. Other techniques include resection and stapling[62] and elliptical seromuscular resection.[63]

However, refashioning the anastomosis or bypass techniques usually fails.[64] Another technique of subtotal duodenal resection with reconstruction of the duodenum by the proximal jejunum as an onlay patch was demonstrated in two children. In this technique, the diseased duodenal wall is completely removed, except for the area of the ampulla of Vater, and the duodenum is reconstructed by the jejunum.[65]

OUTCOME AND LONG-TERM RESULTS

The survival of babies with DO has gradually improved over the last 40 years since the report of surgical correction of intrinsic DO by Ladd in 1932[66] (Table 55.2).[2,6,18,24,28,32,40,46,51,56,58,59] All agree that the three main factors contributing to the mortality rate in this group of patients are as follows: high incidence of associated anomalies, especially severe cardiac malformations; prematurity; and low birth weight.[2,3,32] In a recent review covering 45 years (1951–1995) of management of DO, Murshed et al.[29] found that in the first 15 years, survival reached 51%; in the next 15 years, it was 80%; and in the last 15 years, 95%.

Table 55.2 Survival rates of patients with duodenal atresia and stenosis

Reference	No. patients	% Survival
Wesley and Mahour[46]	72	74
Hancock and Wiseman[24]	34	94
Bailey et al.[18]	138	93
Grosfeld and Rescorla[32]	103	95
Dalla Vecchia et al.[6]	138	86
Cohen-Overbeek et al.[28]	91	91
Choudhry et al.[2]	65	96
Kilbride et al.[40]	51	98
Kay et al.[51,a]	17	100
Hill et al.[56,b]	58	100
Li et al.[58,c]	40	100
Parmentier et al.[60,d]	29	97

Note: Table shows gradual improvement in survival reported over the past 40 years. Most deaths are related to the associated complex cardiac malformations.

[a] Laparoscopic duodenoduodenostomy (years 2004–2008). *N* = 17 pts.

[b] Laparoscopic versus open repair of duodenal obstruction (years 2001–2010). Lap group: *N* = 22 pts, open group: *N* = 36 pts. One patient in the lap group who had Down syndrome, duodenal and jejunal atresias died because of sepsis 5 months after the initial operation.

[c] Laparoscopic duodenoduodenostomy (years 2009–2012). *N* = 40 pts. 20 pts with a diagnosis of congenital intestinal malrotation were operated on by laparoscopic ladd's procedure.

[d] Laparoscopic versus open repair of duodenal obstruction (years 2007–2010). Open group: *N* = 19 pts (years 2013–2014), lap group: *N* = 10 pts.

During the latest period, mortality was almost entirely the consequence of associated anomalies.

Dalla Vechia et al.[6] reported a relatively low rate of postoperative complications in a series of 138 infants. The early complication rate included anastomotic obstruction in 3%, congestive heart failure in 9%, prolonged adynamic ileus in 4%, pneumonia in 5%, and wound infection in 3%.

Late complications included adhesive bowel obstruction in 9%, megaduodenum and duodenal dysmotility that required tapering duodenoplasty in 4%, and gastroesophageal reflux requiring surgery in 5%.

Weber et al.[67] reported the complication rate and morbidity of three methods of technical repair in a group of 41 newborns with duodenal atresia. The three techniques were (1) side-to-side duodenoduodenostomy, (2) side-to-side duodenojejunostomy (which is rarely performed today), and (3) diamond-shaped duodenoduodenostomy. There was no difference in the complication rate, but the diamond-shape technique was found to be superior for repair, resulting in earlier feeding and discharge. Kimura et al.[48] reported on their experience with 44 patients with the diamond-shaped technique, without the use of gastrostomy or transanastomotic tube, and found a very low rate of complications and good long-term results.

Long-term results of congenital DO were reported by Kokkonen et al.[68] who studied 41 patients ages 15–35 years. They found that growth and development, including body weight, were satisfactory. Although the great majority were symptom-free, on barium meal examination, all but two had abnormal findings, including megaduodenum in nine cases. They concluded that some gastrointestinal disturbances are common, even in asymptomatic patients, and careful follow-up is important. Salonen and Makinen[69] reported previously on their experience in a small group of nine patients at age 3–21 years and found, in contrast, a normal barium meal in all groups except one. Their result was similar to the documentation by Kimura et al.[48] with the diamond-shaped technique.

Ein et al.[64] encountered five patients with late complications of duodenal atresia repair that appeared suddenly between the ages of 6 months to 24 years. The duodenal repair was functionally obstructed—caused by proximal, dilated duodenal atony. Plication of the dilated atonic proximal duodenum was curative.

Kay et al.[51] reported on their experience with 17 neonates who underwent laparoscopic duodenoduodenostomy during a 4-year period (2004–2008). There were no conversions to open procedure, no intraoperative complications, and no anastomotic leaks. Time to full feeds in this group averaged 12 days. They concluded that laparoscopic duodenoduodenostomy in the neonate can be safely and successfully performed with excellent short-term outcome. However they emphasized that the laparoscopic duodenoduodenostomy should be performed only by surgeons with adequate laparoscopic skills.

Spilde et al.[57] compared the results of open versus laparoscopic repair of congenital DO of 29 patients during the years 2003–2007. Fourteen patients underwent an

open approach, and 15 patients underwent a laparoscopic operation for the repair of DO. Congenital anomalies were similar between the two groups. The diamond-shaped duodenoduodenostomy technique was performed regardless of surgical approach. Operative time was not significantly different between groups (127 minutes—laparoscopic groups, 96 minutes—open approach). The length of post-operative hospitalization, time to initial feeding, and time to full oral intake were all statistically shorter in the patients undergoing laparoscopic repair. One patient in each group developed a stenosis at the anastomosis. One patient in the open group underwent an open revision of the duodenoduodenostomy, whereas the patient in the laparoscopic group underwent a balloon dilatation of the duodenoduodenostomy via endoscopic gastroduodenoscopy.

It is important to emphasize that the most recent reports of laparoscopic approach for DO are related to the short-term follow-up. As for the long term, there are no results as yet.

Over the last few decades, advancements in neonatal intensive care, parenteral nutrition, management of associated anomalies, and improvements in operative technique including video equipment, smaller instruments, and better postoperative care have improved the outlook for patients born with duodenal atresia and stenosis. Mortality today has been reduced to 5%–10% and is now related mostly to the associated cardiac anomalies.

Intestinal malrotation

AUGUSTO ZANI AND AGOSTINO PIERRO

DEFINITION

Intestinal malrotation is defined as the congenital abnormal positioning of the midgut, whereby the duodenojejunal (DJ) flexure lies right of the midline and relatively close to the ileocecal valve. This makes the dorsal mesenteric root narrow and puts the bowel at risk of midgut volvulus. Intestinal malrotation is usually associated with the presence of peritoneal folds, so-called Ladd's bands, which cross from the colon and cecum to the duodenum and liver and rarely cause duodenal obstruction.

EPIDEMIOLOGY

Malrotation is estimated from autopsy studies to occur in 0.5%–1% of the population, although only 1 in 6000 live births will present with clinical symptoms. Incidence is slightly higher in males than females. Symptoms can occur at any age, but the classical teaching is that the vast majority of patients with malrotation are symptomatic in the first month of life and 90% will present before 1 year of age. However, a study on 2744 cases of intestinal rotation in children up to 17 years of age has shown that only 30% present by 1 month of age, 58% before 1 year of age, and 75% before 5 years of age. A higher incidence of malrotation is seen in patients with anterior abdominal wall defects (gastroschisis and exomphalos), congenital diaphragmatic hernia, heterotaxy syndrome, biliary atresia, intussusception (Waugh's syndrome), intestinal dysmotility syndromes, and small bowel atresia, where this is thought to be the result of an antenatal volvulus.

PATHOGENESIS

Intestinal malrotation results from an arrest of normal rotation of the embryonic gut. The intestine develops in utero through three stages that occur during the first trimester. During the first stage (5th to 10th weeks), the elongating bowel exceeds the abdominal cavity and herniates outside the abdomen. During the second stage (10th to 11th weeks), the bowel returns into the abdomen and rotates 270° counterclockwise around the superior mesenteric artery. The third stage (12th week) is characterized by the retroperitoneal fixation of the duodenum and colon. The distal duodenum comes to lie across the midline toward the left upper quadrant, attached by the ligament of Treitz at the DJ flexure to the posterior abdominal wall. The cecum passes to the right and downward and becomes fixed to the posterior abdominal wall.

CLINICAL PRESENTATION

Patients with intestinal malrotation can remain asymptomatic and be diagnosed incidentally (up to 10% of all cases). Symptomatic infants, instead, may present with signs and symptoms of acute bowel obstruction due to the development of midgut volvulus, which differ according to the age of presentation.

- In the *neonatal period,* babies present with abdominal distention and bilious vomiting. Midgut volvulus results in intestinal strangulation, passage of blood per rectum, and shock. As the strangulation progresses to gangrene, perforation, and peritonitis, the abdominal wall shows signs of edema and discoloration.
- *Older infants* and *children* present with chronic episodic obstructive symptoms, failure to thrive, malabsorption, diarrhea, and/or nonspecific colicky abdominal pain.

DIAGNOSIS

Plain abdominal radiography is usually aspecific, and can either be normal or show features of distended stomach and proximal duodenum with a distal paucity of gas.

If the physical examination and/or the abdominal radiography is indicative of volvulus with high suspicion,

surgery should be expedited. Alternatively, if the patient is stable, further diagnostic imaging is recommended.

Upper gastrointestinal contrast study is the gold-standard investigation for patients presenting with signs of proximal bowel. Findings in intestinal malrotation are as follows:

- On frontal view, DJ flexure on the right of the spine and inferior to the transpyloric plane (Addison's plane).
- On lateral view, the fourth part of the duodenum lies anterior to the second part (D2), occasionally showing a corkscrew appearance.

Contrast enema has historically been used, especially to study the position of the cecal pole. However, in 15%–30% of malrotation cases, the cecum is normally located, and in many patients with normal intestinal rotation, the cecum has an abnormal location. Therefore, a contrast enema is not always helpful.

Abdominal ultrasonography that demonstrates an abnormal orientation of the mesenteric vessels can also be indicative of intestinal malrotation. In a normal situation, the superior mesenteric vein is located to the right of the superior mesenteric artery. Hence, a reversed arrangement of these vessels is suggestive of malrotation. Color Doppler ultrasonography may reveal a "whirlpool sign," which is created when the superior mesenteric vein and the mesentery wrap around the superior mesenteric artery in midgut volvulus. Ancillary ultrasonographic findings suggestive of malrotation are found when looking at the third part of the duodenum: dilatation of the proximal portion indicating obstruction and abnormal position between the superior mesenteric artery and the aorta in the retroperitoneal space are suggestive of malrotation.

Computed tomography of the abdomen is commonly used in adults as it also provides information on bowel perfusion. However, this imaging technique should not be employed in infants, children, and adolescents due to the radiation exposure risk.

TREATMENT

Management of the asymptomatic patient and timing of surgery remain controversial and are discussed in the following paragraph.

All symptomatic patients with positive investigative findings should undergo urgent laparotomy following a brief period of intensive resuscitation, with crystalloids or 5% human albumin in the form of a bolus (20 mL/kg to repeat as required) and maintenance fluids. A nasogastric tube is passed to aspirate gastric content and avoid aspiration. Blood is drawn for crossmatch, full blood count, and electrolytes. Blood for transfusion should be available at the commencement of surgery.

SURGERY

The principles of the procedure have remained almost unchanged since originally described by Ladd in 1936.

Open Ladd's procedure

The patient is positioned supine, and a right-upper-quadrant transverse incision is made. The umbilical vein is divided and ligated. The peritoneal fluid is examined. Frequently it is clear; blood-stained fluid implies bowel ischemia and volvulus; fecal staining indicates bowel perforation and should be cultured. The midgut is delivered from the wound and the base examined. Any volvulus should be derotated counterclockwise, noting the number of turns. The bowel is examined for viability, and any ischemic bowel should be wrapped in a damp swab and reexamined after 5–10 min. Nonviable bowel is resected and a primary anastomosis performed.

Ladd's bands, if present, are divided. The superior mesenteric artery is identified, and the mesenteric base is broadened as much as possible by division of the peritoneal folds. Care must be taken not to injure the superior mesenteric vessels. An appendectomy should be performed, due to the abnormal position of the appendix at the end of the surgery (left upper quadrant). However, it is still a matter of debate whether an appendectomy should be performed in neonates. Some surgeons would opt for an inversion of the appendix; others would leave the appendix untouched to prevent potential additional morbidity.

At the end of the procedure, the small bowel is placed in the right hemiabdomen and the large bowel in the left hemiabdomen. There is no need to apply any fixation sutures, as adhesions and the broad base to the mesentery developed by Ladd's procedure usually stabilize the bowel. The abdomen is closed as routine.

Midgut volvulus due to malrotation may result in loss of the small bowel. The author has reported a technique to deal with mesenteric thrombosis, which causes continuing ischemia of the intestine. This technique includes the following: (1) digital massage of the superior mesenteric vessels after derotation to restore intestinal perfusion and (2) postoperative systemic infusion of tissue-type plasminogen activator. If extensive ischemic bowel of doubtful viability is present, a second-look laparotomy is performed after 24 h in the hope of minimizing the extent of bowel resection required.

Laparoscopic Ladd's procedure

Laparoscopy can be performed for diagnosis of equivocal cases of malrotation as well as for correction of the defect. The principles of the procedure are the same as the open technique. Care must be taken to correctly identify landmarks such as the duodenum and ascending colon. To gain access to the duodenum, it is useful to raise the head of the operating table and elevate the right flank. The ascending colon falls toward the left side of the abdomen. The duodenum is exposed, and Ladd's bands are divided. After division, the bowel is examined along its length for any further causes of obstruction. Dividing the peritoneal folds broadens the root of the mesentery, and care must be taken in not injuring the superior mesenteric vein. Appendectomy is

carried out either using endoloops for intracorporeal ligation or by delivering the appendix through a trocar site and excising it extra-abdominally in smaller patients.

Postoperatively, a nasogastric tube is left in situ for gastric aspirates. Intravenous fluids are continued, and gastric losses are replaced milliliter for milliliter with normal saline and potassium chloride (20 mmol/L saline). Enteral feeds are restarted when the postoperative ileus is resolved.

COMPLICATIONS

Recurrence of midgut volvulus is rare but has been reported and may be due to division of Ladd's bands without a full derotation and splaying of the mesentery. Adhesive bowel obstruction is reported in about 5% of cases. Midgut volvulus occurs in 45%–65% of children with malrotation and still carries a mortality rate of 7%–15%; necrosis of >75% of the midgut is associated with intestinal failure.

CONTROVERSIES

Management of asymptomatic patients remains controversial. It is still a matter of debate whether to look for and/or correct rotation anomalies in the following:

- Patients undergoing repair of abdominal wall defects or congenital diaphragmatic hernia. Some degree of nonrotation or malrotation is invariably encountered in these patients, and subsequent volvulus is rare.
- Asymptomatic patients with malrotation in whom the diagnosis is made incidentally during evaluation for nonspecific complaints, prior to fundoplication for gastroesophageal reflux, and in those with heterotaxy syndromes.
- Monozygotic twins with proven malrotation in the sibling.

Congenital hyperinsulinism

PAUL R. V. JOHNSON

INTRODUCTION

Congenital hyperinsulinism (CHI), previously termed persistent hyperinsulinemic hyperglycemia of infancy (PHHI), is a spectrum of conditions characterized by profound hypoglycemia in the presence of inappropriately high insulin secretion.[1,2] Although rare overall, CHI is a significant cause of hypoglycaemic brain injury in the newborn[1] and subsequent mental retardation,[3] and therefore, all those involved in the medical and surgical management of neonates need to be familiar with this condition so that the diagnosis can be made promptly, and early treatment implemented. This chapter provides an overview of the etiology, clinical presentation, diagnosis, and management of CHI to facilitate this.

ETIOLOGY

Over the past decade, our understanding of the etiology of CHI has increased enormously.[4,5] This has not only led to more focused treatment for certain subforms of the condition but has also meant that genetic counseling can be offered to some families. CHI can either occur sporadically with an incidence of 1 in 40,000–50,000 or can be familial with an incidence as high as 1 in 2500. Genetically, CHI is a heterogeneous condition, and mutations of 11 different genes related to insulin secretion have now been reported.[5] Mutations can be sporadic, autosomal recessive, or autosomal dominant. The most common abnormality underlying CHI is a dysfunction of the ATP-sensitive potassium channel within the pancreatic beta cell (channelopathies).[6] This ion channel is composed of two subunits, each of which is encoded for by a different gene, namely the sulfonylurea receptor gene *SUR1* and the inward-rectifying potassium channel gene *KIR6.2*. Mutations of the SUR1 gene account for 50%–60% of CHI, whereas mutations of the KIR6.2 gene are less common and only responsible for 10%–15% of cases.[7] The abnormal potassium channel results in the beta cell being in a constant state of depolarization, and therefore, it is constantly secreting insulin despite the cell environment being one of hypoglycemia (Figure 57.1a and b). A less common group of underlying causes of CHI are the "metabolopathies," which result from enzyme deficiencies (e.g., glutamate dehydrogenase [GDH], glucokinase [GK] or short-chain L-3-hydroxyacyl-CoA dehydrogenase [SCHAD]) or dysfunction of the insulin receptor. Finally, CHI can be associated with certain specific syndromes such as Beckwith–Wiedemann syndrome, Periman syndrome, and Sotos syndrome, each of which has associated chromosomal abnormalities.

PATHOLOGY

The original term for CHI was nesidioblastosis. This term was created by Laidlaw[8] in 1938, and described the histological finding of islet cells proliferating by budding off the pancreatic ductal tissue within pancreases of infants with severe symptoms of hypoglycemia. However, this term has since been abandoned as it was realized not only that CHI represents a spectrum of different disorders, but more specifically, that many normal neonatal pancreases also exhibit nesidioblastosis.[9]

However, the most important advance in our understanding of CHI over recent years has been the discovery that there are two distinct histopathological forms, namely, a focal form and a diffuse form. Focal CHI is characterized by a focal hyperplasia of the pancreatic beta cells and is to be distinguished from the more discrete adenoma or insulinoma seen in older children or adults. Normal islets are seen outside the focal abnormality (Figure 57.2). In the diffuse form of CHI, the islets are abnormal throughout the whole pancreas and exhibit large, pleomorphic, hyperchromatic nuclei (Figure 57.3). Distinguishing focal from diffuse CHI is important to ensure that the correct surgical treatment is undertaken.

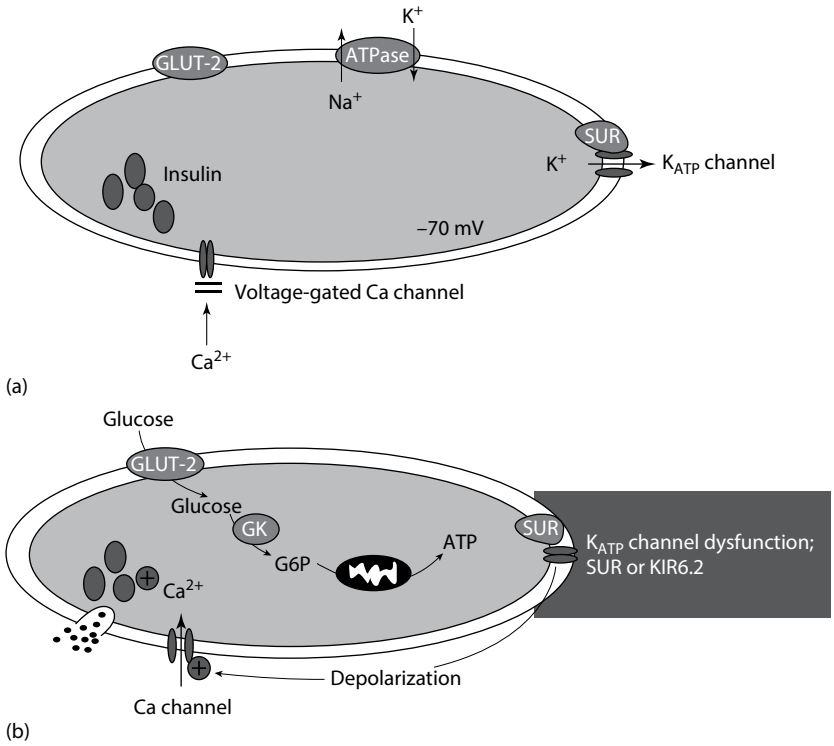

Figure 57.1 **(a)** Normal resting beta cell. At rest, the normal K_{ATP} channel is closed, which maintains the membrane potential at –70 mV. This results in the calcium channels remaining closed, preventing any calcium influx or consequent insulin release. **(b)** Congenital hyperinsulinism (CHI) beta cell. The abnormal K_{ATP} channel in the nonstimulated CHI beta cell results in the channel remaining closed even at rest. This causes depolarization of the membrane and opening of the calcium channel. The consequent calcium influx results in insulin degranulation and release.

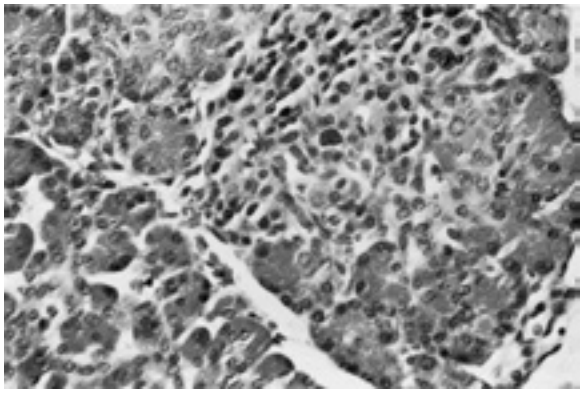

Figure 57.2 Diffuse congenital hyperinsulinism: islets have large, pleomorphic, hyperchromatic nuclei present throughout pancreas.

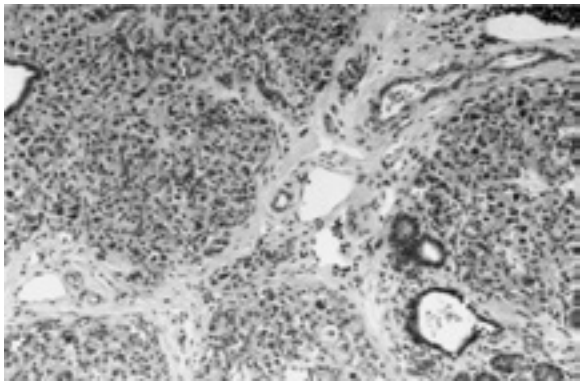

Figure 57.3 Focal congenital hyperinsulinism: nodules of adenomatous islet cell hyperplasia with normal islets outside the lesion.

CLINICAL PRESENTATION

CHI usually presents within the first few hours or days of life in both premature and term babies but can occasionally present later in infancy or childhood.[7] Babies can present with nonspecific symptoms of hypoglycemia such as poor feeding, irritability, or lethargy, or more severe symptoms such as seizures or coma. Apnea can also occur. This outlines the importance of all neonates undergoing blood glucose testing shortly after birth. Antenatal hyperinsulinism can have a profound effect on fetal development; a proportion of babies with CHI are macrosomic due to increased glycogen storage, and some have organomegaly. Some also present with mild facial abnormalities such as a high forehead, a small nasal tip, and a short columella.[10] CHI is most commonly an isolated condition but can be associated with certain specific syndromes as described earlier. CHI can sometimes be transient rather than persistent, but it is the persistent forms that are of most relevance to surgeons.

DIAGNOSIS

CHI is characterized by hyperinsulinemic, hypoketotic, hypofattyacidemic hypoglycemia.[1] The following diagnostic criteria are used: (1) laboratory blood glucose readings of <3.5 mmol/L (63 mg/dL)[11] (the diagnostic level used to be defined as 2.5–3 mmol); (2) a glucose infusion rate of >8 mg kg^{-1} min^{-1} (normal range is 4–6 mg kg^{-1} min^{-1}); (3) unsuppressed insulin concentrations of >1 mU/L; (4) a positive response to the subcutaneous or intramuscular administration of glucagon (plasma glucose concentrations increasing by 2–3 mmol/L following a 0.5 mg subcutaneous glucagon injection); and (5) negative ketone bodies in the plasma and urine.

Previously, the definitive investigation used to distinguish diffuse and focal forms of the disease was serial venous sampling of insulin. However, this procedure was invasive and time-consuming, and often resulted in inaccurate localization of focal disease. Over the last decade, the gold-standard investigation has become [^{18}F]-DOPA positron emission tomography (PET) combined with computed tomographic (CT) angiography with 3-D reconstruction.[12,13] This test is noninvasive, is both sensitive and specific, and gives excellent localization of focal lesions. However, the [^{18}F]-fluoro-L-DOPA isotope is only currently available in a limited number of centers.

MANAGEMENT

The main aim of management is to prevent hypoglycemic brain damage and to allow normal psychomotor development. In mild cases, it may be possible to maintain acceptable levels of blood glucose by dietary measures alone. In the majority of cases, however, intravenous administration of high concentrations of glucose are required to maintain blood glucose levels above 2.6 mmol/L. Glucose infusion rates in excess of 20 mg kg^{-1} min^{-1}, i.e., 15%–20% glucose, may be required. In these cases, it is essential to insert a central venous catheter to provide a central route for administration of high concentrations of glucose and to allow frequent monitoring of blood glucose levels.

Medical management

Diazoxide is the first-line medical treatment and is an agonist of the K_{ATP} channel. It is commenced at a dose of 5–20 mg kg^{-1} day^{-1} in three divided doses. It can be highly effective in the treatment of the transient and syndromic forms of CHI, but in the more severe neonatal forms in which a mutation of the K_{ATP} channel is present, the beta cells may be unresponsive.[7–14] Diazoxide is usually used in conjunction with chlorthiazide at a dose of 7–10 mg kg^{-1} day^{-1} in two divided doses. These two agents exert a synergistic effect on the K_{ATP} channel with diazoxide. Octreotide is a long-acting analogue of the pancreatic hormone somatostatin and is used in CHI both as a short-term measure to stabilize the baby pending definitive treatment and, sometimes, as a long-term treatment combined with frequent feeding, for diffuse disease. Subcutaneous or intravenous glucagon is used in the acute management of hypoglycemia, often in combination with octreotide. The calcium channel blocker nifedipine has been used successfully in a small number of patients.[15] The aim of using such an agent is to reduce the calcium flux resulting from the constant depolarization of beta cells in CHI. The systemic effect of calcium blockade can be restrictive. Recently, several groups have successfully managed to treat small numbers of children with CHI with the immunosuppressive agent sirolimus (rapamycin), an inhibitor of interleukin 2 (IL-2) and other cytokines.[16]

Surgical management

Surgical treatment is indicated when an infant remains dependent on intravenous glucose administration despite maximum medical treatment. Whereas 95% pancreatectomy was, until recently, the treatment of choice for all cases of CHI that were unresponsive to medical treatment,[17] improvements in our understanding of the histopathology of CHI have enabled more limited and targeted surgical resection treatment to be used for the focal form of the disease.[18,19] Pancreatectomy can be performed using traditional open operative techniques or can be undertaken using laparoscopic techniques.[20,21] The surgical principles are the same for both techniques.

INCISION

For the open technique, a laparotomy is performed via a generous supraumbilical transverse muscle-cutting incision, extending through both rectus abdominis muscles (Figure 57.4). For the laparoscopic approach, a three-trocar technique is used with triangulation centered around the umbilicus. Within the peritoneum, a thorough search is made for sites of ectopic pancreatic tissue.

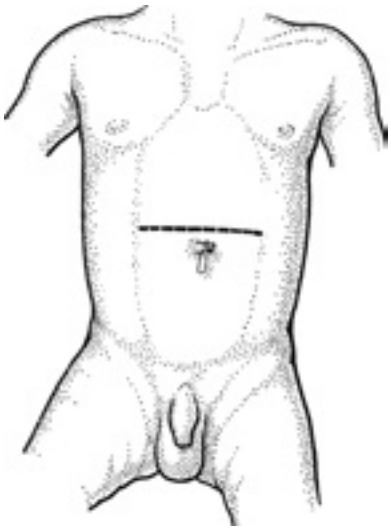

Figure 57.4 Transverse upper abdominal incision extending across both rectus abdominis muscles.

Figure 57.5 Exposure of the head, body, and tail of the pancreas by entering the lesser sac dividing the vessels in the greater omentum along the greater curvature of the stomach.

EXPOSURE

The anterior surface of the pancreas is exposed by entering the lesser peritoneal sac via the gastrocolic omentum, ligating and dividing vessels in the greater omentum along the greater curvature of the stomach (Figure 57.5). The tail of the pancreas lies in the hilum of the spleen. The hepatic flexure is reflected medially and the duodenum Kocherized to expose the head of the pancreas. The entire pancreas is carefully examined or inspected.

95% PANCREATECTOMY

In the diffuse form, the dissection of the pancreas proceeds medially from the tail toward the neck of the pancreas, which lies just to the right of the superior mesenteric vessels. It is essential for future immunologic competence to preserve the spleen whenever possible. This is accomplished by carefully exposing the short pancreatic vessels passing from the splenic vessels to the pancreas. These vessels, especially the veins, are extremely friable, but meticulous dissection will allow individual ligation, application of metal clips or electrocoagulation, and division of the vessels without traumatizing the main vessels (Figure 57.6). Should hemorrhage occur from damage to the splenic vein, direct repair should be attempted. In the event of failure to achieve hemostasis, ligation of the splenic vein with preservation of the splenic function can be expected due to collateral supply from the short gastric vessels. When the dissection has progressed to the right of the superior mesenteric vessels, attention is directed to the head of the pancreas and in particular the uncinate process (Figure 57.7).

The uncinate process is carefully dissected from behind the superior mesenteric vessels, and after positively defining the course of the common bile duct, the head of the pancreas to the left of the common duct and in the concavity of the duodenal loop is excised, leaving a sliver of pancreatic tissue on the surface of the duodenum and on the left wall of the common duct. The pancreatic duct is identified and ligated

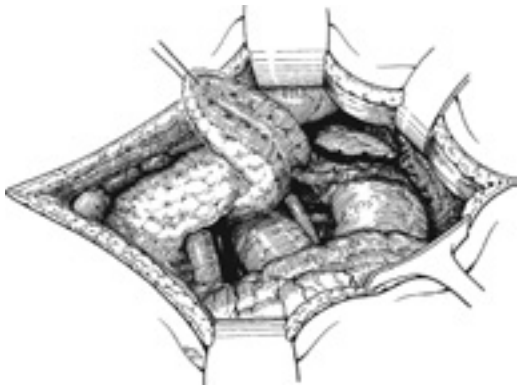

Figure 57.6 The short pancreatic vessels arising from the splenic vessels are divided, and the body and tail of the pancreas are gradually dissected toward the head.

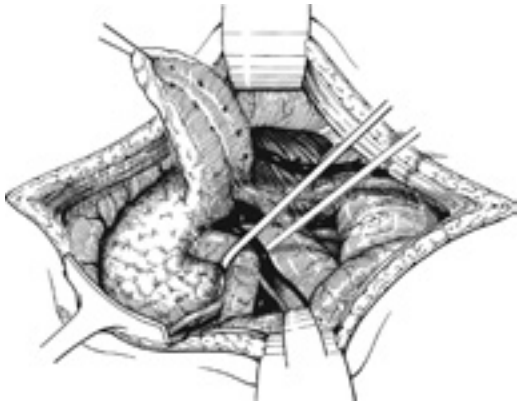

Figure 57.7 The superior mesenteric vessels are displayed and retracted toward the left, exposing the uncinate process of the pancreas.

with a nonabsorbable ligature. Hemostasis is carefully and meticulously achieved. The remaining pancreatic tissue consists of that part of the gland between the duodenum and the common bile duct and the sliver of tissue on the medial wall of the second part of the duodenum (Figure 57.8). This represents approximately 5% of the total volume of the pancreas but can vary considerably from patient to patient. A suction drain via a separate stab incision is left in the pancreatic bed.

Laparoscopic resection is performed in a similar manner, but it is easiest to perform the resection using a hook diathermy in a piecemeal manner, using a stay suture at different intervals along the pancreas as dissection proceeds from the pancreatic tail toward the head. For the transection of the pancreas itself, the harmonic scalpel ensures good hemostasis and occlusion of the pancreatic duct and cut parenchyma.

RESECTION OF FOCAL DISEASE

Exactly the same principles as described earlier apply for resection of focal disease. Based on the preoperative PET scan, the focal lesion is resected leaving the normal pancreas behind.[19] If the focal disease is within the head of the pancreas, occasionally, a major Whipple-type resection is required.

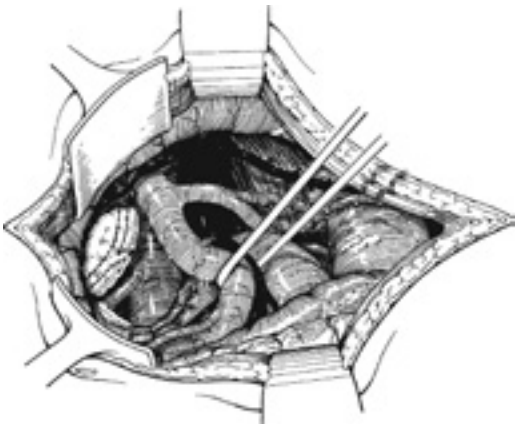

Figure 57.8 Final appearance following 95% pancreatectomy. The only remaining pancreatic tissue lies to the left of the common bile duct and a sliver in the C-curvature of the duodenum. Note splenic vessels and the completed excision of the uncinate process.

POSTOPERATIVE CARE

Postoperatively, glucose infusions and CHI medications are directed by constant monitoring of blood glucose. The infant is kept nil by mouth with a nasogastric tube in situ until the postoperative ileus has resolved.

COMPLICATIONS

Each of the medical treatments of CHI can have its side effects.[7] Long-term use of diazoxide is associated with hypertrichosis (excessive growth of hair in areas where hair does not normally grow), and this can limit its long-term use. Octreotide is associated with a wide range of side effects including gastrointestinal upset (abdominal pain, nausea, bloating, and diarrhea), and suppression of growth hormone (GH), thyroid-stimulating hormone (TSH), and adrenocorticotropic hormone (ACTH). Recurrent hypoglycemia can occur as a result of insufficient surgical resection of the diffuse form of the disease, or due to failed localization in the focal form, and should be evident within the first 72 hours after the operation. Persistent hypoglycemia may require further surgical resection. Other surgical complications include postoperative infection, bleeding, and operative trauma to the bile duct.[22] If the latter is diagnosed preoperatively, then primary repair and drainage is performed. Delayed diagnosis of bile duct injury can be treated operatively or conservatively depending on the degree of damage and the timing of presentation.

LONG-TERM RESULTS

The neurological outcome of patients with CHI depends on the age of presentation.[3] Neonates with unresponsive CHI that is unresponsive to medical treatment are at increased risk of brain injury, as are those with a delayed diagnosis and delayed implementation of treatment.[3] The form of CHI per se does not seem to influence outcome. In patients undergoing 95% pancreatectomy, the majority will develop insulin-dependent diabetes by the second decade of life.[23,24] These patients require close monitoring of their glucose homeostasis, and a yearly glucose-tolerance test is indicated. For those that do develop diabetes, novel, minimally invasive treatments such as pancreatic islet transplantation are now achieving excellent results for reversing insulin-requiring diabetes in adults.[25] The majority of these patients will require oral pancreatic exocrine replacement. The recent emphasis on limited pancreatic resection for focal CHI means that both exocrine and endocrine insufficiency can be reduced in this group of patients. Good outcomes have been reported in this group of patients.[26]

Jejunoileal atresia and stenosis

ALASTAIR J. W. MILLAR, ALP NUMANOGLU, AND SHARON COX

INTRODUCTION

Jejunoileal atresia, defined as a congenital defect in continuity of the small bowel, is a common cause of intestinal obstruction in the newborn.[1–3] The incidence of jejunoileal atresia varies between 1 in 1500 and 1 in 3000 live births.[4] Jejunoileal occlusions occur more frequently than duodenal or colonic atresias.[1,5] With improved neonatal and perioperative care, safe anesthesia, refined surgical techniques, and management of short bowel syndrome, a survival rate of greater than 90% can be expected in well-resourced centers. At the Red Cross War Memorial Children's Hospital in Cape Town during the 56 years from 1959 to 2015, 363 jejunoileal atresias, 275 (76%) jejunum and 88 (24%) ileum, were seen (Table 58.1). The mortality rate was initially high, and it was only in the mid-1950s that an improved understanding of the pathogenesis and pathology of the condition led to innovative surgical techniques, which resulted in greatly improved surgical outcome.[4–6]

ETIOLOGY

In 1889, Bland Sutton postulated that atresia occurred at the site of "obliterative embryological events," and he quoted atrophy of the vitelline duct.[7] In 1900, Tandler,[8] supported by embryonal studies, suggested that intestinal atresia was related to a lack of recanalization of the solid stage of the intestine, while others have questioned these theories.[9–11] In 1952, Louw[4] published the results of an investigation of 79 patients treated at Great Ormond Street, London, and suggested that jejunoileal atresia was probably due to a vascular accident rather than the result of inadequate recanalization. At his instigation, Barnard perfected the experimental model in pregnant mongrel bitches. Mesenteric vascular insults, such as volvulus, intussusception, and interference with the blood supply to a segment of bowel, were created in the dog fetus.[12] This not only confirmed the hypothesis but led to a change in the surgical procedure for correcting atresias and stenoses of the jejunum and ileum with a marked improvement in outcome.[13–15] Subsequently, these experimental findings were confirmed by others in several different animal models and in clinical practice.[16–20] Evidence of bowel infarction was present in 42% of 449 cases of jejunoileal atresia in a collected series, which further supported the vascular hypothesis.[21] Furthermore, the localized nature of the vascular accident occurring late in fetal life would explain the low incidence (less than 10%) of coexisting abnormalities of extra-abdominal organs.

The family history may help to identify hereditary forms and conditions that may predispose to atresia, i.e., cystic fibrosis and anomalies of intestinal rotation. The anomaly is usually not genetically determined, although affected monozygotic twins and siblings have been described.[22] A genetic basis has been established for type IIIb and IV multiple atresias.[22–27] In this situation patients typically present as premature, low-birth-weight babies and have associated malrotation and other congenital abnormalities. Sporadic jejunoileal atresia is different from the familial multiple atresias of the whole gastrointestinal tract seen in severe immune deficiency syndrome, which is an autosomal recessive condition.[28] Down syndrome is most uncommon in babies with jejunoileal atresia compared with duodenal atresias.

A classification system for familial intestinal atresia has been proposed that suggests that most cases result from disruption of a normal embryologic pathway in the development of the superior mesenteric artery and its branches.[29]

EPIDEMIOLOGY

In a 16-year study of cases documented in 20 EUROCAT registers, cases with a normal karyotype had a prevalence of 0.7 per 10,000 live births for jejunoileal atresia.[30] This is much lower than reported rates in previous studies and different geographical locations.[4] Small intestinal atresia prevalence varies in different geographical areas, but there does not seem to be any significant trend in prevalence over time. There is

Table 58.1 Jejunal atresia and stenosis: Red Cross War Memorial Children's Hospital, experience from 1959 to December 2015

Type	Jejunum	Ileum	Total	Types as % of total	% Mortality related to type
Stenosis	22	14	36	10	0
Type I	68	18	86	24	5
Type II	22	14	36	10	11
Type IIIa	28	27	55	15	15
Type IIIb	68	1	69	19	17
Type IV	67	14	81	22	12
Total	275	88	363	100	10

Note: Last 25-year survival (1990–2015) was 92% (147/160).

weak evidence of an increased risk in mothers aged less than 20 years compared with mothers aged 20–29 years.[30]

PATHOLOGY

The classification of jejunoileal atresia into three types by Bland Sutton in 1889 has stood the test of time, except for the subdivision of type III into two categories (a and b) and the addition of type IV (Figure 58.1).[7,31,32] This subdivision has allowed a better long-term prognostication. In stenosis, the proximal dilated and narrower distal bowel are in continuity with an intact mesentery, but at the point of junction, there is a short, narrow, somewhat rigid segment with a narrow but patent lumen. The small intestine is of normal length (Figure 58.2).

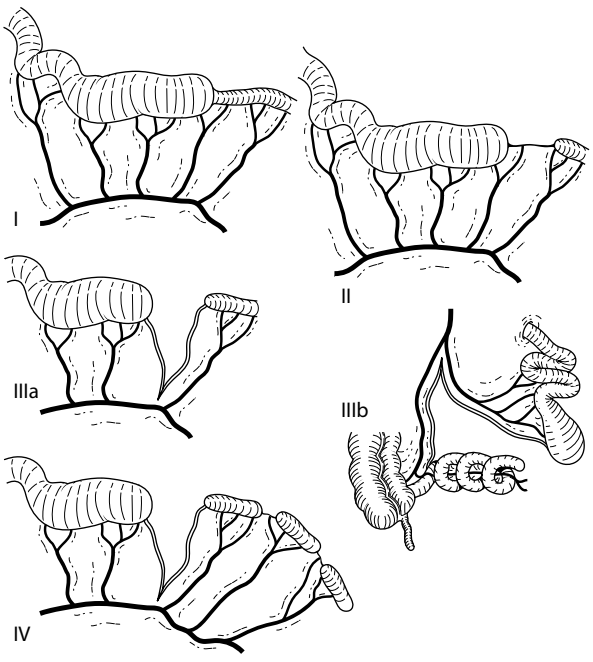

Figure 58.1 The different types of small bowel atresia according to the modified classification by Grosfeld. (From Grosfeld JL et al., Operative management of intestinal atresia and stenosis based on pathologic findings, *J Pediatr Surg* 1979;14(3):368–75.)

Figure 58.2 The clinical appearance of stenosis.

In atresia type I (membrane or web) (Figure 58.3a and b), the dilated proximal and collapsed bowel are in continuity, and the mesentery is intact. The intraluminal pressure in the proximal bowel produces bulging of the web into the distal intestine so that the transition from the distended to the collapsed bowel is conical in appearance—the "windsock" effect. The distal bowel is completely collapsed, and the small intestine is of normal length.

In atresia type II (blind ends joined by a fibrous band) (Figure 58.4a and b), the proximal bowel terminates in a bulbous blind end, which is grossly distended and hypertrophied for several centimeters and is often hypoperistaltic. The bowel proximal to this is usually also considerably distended and hypertrophied for a further 5–10 cm. More proximally, the bowel distension is less marked, and the bowel assumes a normal appearance. The distal collapsed bowel commences as a blind end, which is sometimes bulbous due to remains of a fetal intussusception. The two blind ends are joined by a thin fibrous band. The corresponding intestinal mesentery is normal but may occasionally be deficient, leaving a V-shaped gap. The small intestine is usually of normal length.

In atresia type IIIa (disconnected blind ends) (Figure 58.5a and b), the appearance is similar to that in type II, but the blind ends are completely separate. There is always a V-shaped gap in the mesentery, and the total bowel length is reduced.

In atresia type IIIb ("apple-peel,"[17] "Christmas tree,"[33] or "Maypole"[5] deformity), as in IIIa, the blind ends are disconnected, and the mesenteric defect is substantial

(b)

Figure 58.4 **(a)** Diagram of atresia type II. Blind ends joined by a band with an intact mesentery and normal length of bowel. **(b)** Operative photograph of a resected specimen of proximal dilated loop, band of mesentery, and 3 cm of distal collapsed bowel.

(Figure 58.6a, b, and c). This type is the consequence of an extensive infarction of the midgut secondary to a superior mesenteric artery occlusion just distal to the middle colic origin, producing a proximal jejunal atresia with loss of a varying segment of jejunum. The distal ileum remains viable, receiving an often precarious blood supply from the arterial supply to the right colon, around which the ileum is coiled. Occasionally, additional type I or type II atresias are found along the coiled length of bowel toward the distal blind end. There is always a significant reduction in intestinal length. These babies are usually born prematurely and of low birth weight. In addition, they may have associated bowel anomalies such as malrotation and may develop short bowel syndrome with increased morbidity and mortality.[21] A familial incidence has been reported by some authors.[22,34]

In atresia type IV, multiple atresias are present, which could be a combination of types I–III and often have the appearance of a string of sausages (Figure 58.7a and b). The bowel length is usually reduced. The site of the most proximal atresia determines whether it is classified as jejunal or ileal atresia.

In all types, the intestine proximal to the obstruction becomes dilated and hypertrophied. This dilated bowel frequently has a cyanosed appearance and may have some necrotic areas from either sustained intraluminal pressure or secondary volvulus. Perforation may develop antenatally, leading to meconium peritonitis, or may occur as a postnatal event, especially if diagnosis is delayed.

The peristaltic movements in the proximal segment are subnormal and ineffective, and histologic and histochemical abnormalities can be observed up to 20 cm cephalad to the atretic segment.[35,36] Recent histological and immunohistochemical studies have revealed changes in morphology and density of the enteric nervous system and interstitial cells of Cajal in the bowel both proximal and distal to the atresia.[37] In addition, pathological deterioration of the myenteric ganglia, nerve growth factor, and interstitial cells of Cajal occurs for up to 15 cm proximal and 3 cm distal to the atresia, and these changes may cause intestinal motility problems after surgical repair.[38] Macroscopically, the distal bowel is unused and wormlike in appearance but potentially normal in length and function.

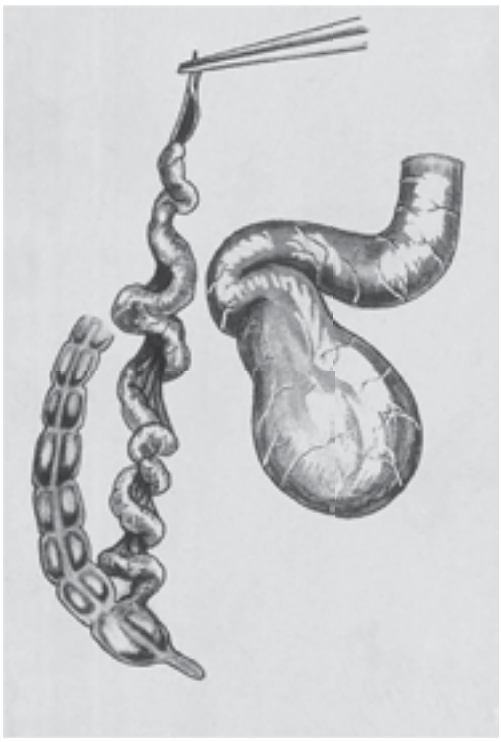
(a)

(b)

Figure 58.5 (**a** and **b**) Atresia type IIIa. Blind ends disconnected with a V-shaped defect in the mesentery. The bowel length is reduced. The grossly dilated obstructed bowel tapers proximally into intestine of normal calibre. The distal collapsed bowel illustrates how difficult it may be to assess the length of this segment.

PRENATAL DIAGNOSIS

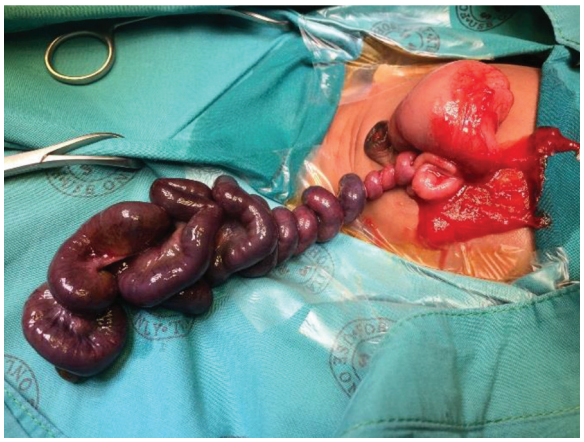
A prenatal history of polyhydramnios is frequent. Up to 38% of patients with proximal jejunal atresia display polyhydramnios, which is less frequent in more distal cases. Many babies with intestinal atresia are diagnosed by ultrasound investigation of the fetus, which shows a dilated, echogenic, and thickened bowel loop with increased peristalsis. The distal bowel is decompressed.[39] Unfortunately, ultrasonic prenatal diagnosis has a relatively poor predictive value especially in early gestational age, and in addition, the detection is highly variable, ranging from 10% to 100%, with an overall prediction of 51% in a recent meta-analysis, jejunal atresias being detected more often than ileal atresias.[40] The use of fetal MRI scanning is increasing and may be more valuable in the prenatal diagnosis of bowel atresia.[41]



(a)

(b)

Figure 58.6 (**a** and **b**) Atresia type IIIb with a gross mesenteric defect and the coiled distal ileum with precarious collateral blood supply, producing the typical "apple-peel" appearance. Note the precarious blood supply of the terminal portion of the distal bowel and the grossly dilated proximal jejunum. There is always significant reduction in intestinal length. (*Continued*)



(c)

Figure 58.6 (Continued) **(c)** Type IIIb jejunal atresia with necrotic bowel at the time of initial exploration. The resulting viable bowel length may be incompatible with eventual enteral autonomy, but long-term survival may be achieved provided there is a short segment of viable terminal ileum and an intact ileocecal valve remaining.

(b)

Figure 58.7 **(a)** Type IV atresia. **(b)** Operative photograph shows multiple atresias with a typical "string of sausages." The bowel length is usually reduced.

CLINICAL FEATURES

Atresia or severe stenosis of the small intestine presents clinically as neonatal intestinal obstruction with persistent bile-stained vomiting dated from the first or second day of life. In general, the higher the level of obstruction, the earlier and more forceful the vomiting, whereas in low intestinal obstruction, the vomiting may be delayed. Abdominal distension is frequently present, more so with the distal ileal intestinal atresias, where the distension is generalized, compared with the more proximal jejunal atresias, where it is confined to the upper abdomen and is relieved by nasogastric tube aspiration. In delayed diagnosis or where perforation has occurred, the distension may be severe and associated with respiratory distress. Constipation is usually not absolute, and the meconium passed varies from normal in color to the more common grey plugs of mucus. Occasionally, if ischemic bowel is present, as in type IIIb atresia, blood may be passed rectally.

Diseases that can mimic jejunoileal atresia include midgut volvulus, meconium ileus, duplication cysts, internal hernia, ileus due to sepsis, birth trauma, prematurity, and transplacental crossing of maternal medication.

Erect and supine abdominal radiographs will reveal distended small bowel loops and air–fluid levels (Figure 58.8a). The lower the obstruction, the greater the distended loops of bowel and the more fluid levels will be observed. A single large loop of bowel and air–fluid level would indicate atresia rather than other causes of neonatal intestinal obstruction. A prone lateral view is useful to distinguish between low small bowel and colonic obstruction. In some instances, the first abdominal radiograph may reveal a completely opaque abdomen due to a fluid-filled obstructed bowel. Emptying of the stomach by means of a nasogastric tube and injection of air will demonstrate the level of the obstruction. With intestinal stenosis, the calibre of the proximal obstructed intestine is greater than that of the distal gut, but because the obstruction is incomplete, the diagnosis is often delayed. When the abdominal radiograph suggests a complete obstruction, a contrast enema may be performed to exclude colonic atresia, distinguish between small and large bowel distension, determine whether the colon has the typical microcolon appearance, and locate the position of the cecum as an indication of malrotation. It also makes saline injection of the colon at surgery unnecessary, a sometimes tedious maneuver.

The classical appearance of the colon distal to jejunoileal atresia is that of an unused colon or microcolon (Figure 58.8b). When an incomplete small bowel obstruction is diagnosed, an upper gastrointestinal contrast study is indicated to demonstrate the site and nature of the obstruction. Malrotation may also be observed in 10%–30% of babies with jejunoileal atresia. Occasionally, dystrophic intraperitoneal calcification of meconium peritonitis may be seen on plain radiograph, signifying intrauterine bowel perforation. If the atresia has formed late in intrauterine life, the bowel distal to the atresia may assume the calibre of a used colon.

(a)

(b)

Figure 58.8 **(a)** Erect abdominal radiograph of a newborn infant showing obstructed upper small bowel loops with fluid levels. No air is visible in the distal bowel. **(b)** Contrast enema showing the unused or microcolon distal to a jejunoileal atresia. In addition, evidence of malrotation is present.

GUIDELINES FOR MANAGEMENT

The guidelines for management of jejunoileal atresia are as summarized in Table 58.2.

Table 58.2 Guidelines for management of jejunoileal atresia

Prenatal	Polyhydramnios, affected family: ultrasonography, MRI
Preoperative management	Gastric decompression
	Fluid management: maintenance and replacement
	Correction of electrolyte abnormalities
	Radiology: Abdominal radiograph, contrast enema
	Correction of hematological and biochemical abnormalities
	Prophylactic antibiotics
Operative management	Identify type of atresia
	Bulbous component: resect, taper, or plicate if short residual length
	Derotate and taper if high jejunal atresia
	Preserve maximal distal bowel length—measure residual bowel
	Establish patency of distal bowel with saline injection
	End-to-end single-layer interrupted anastomosis
Postoperative Management	Gastrointestinal decompression
	Antibiotics
	Parenteral nutrition
	Early graduated enteral feeds: breast, special, or polymeric feeds
	Surveillance for gastrointestinal dysfunction
Special problems	Anastomotic dysfunction
	Short bowel syndrome
	Associated congenital abnormalities

Source: Adapted from Haller JA Jr. et al., Intestinal atresia. Current concepts of pathogenesis, pathophysiology, and operative management, *Am Surg* 1983;49(7):385–91.

TREATMENT

The newborn baby tolerates operative intervention all the better after a few hours of preoperative preparation, especially if the diagnosis has been delayed. In general, this preparation should pay particular attention to hypothermia, hypoxia, hypovolemia, hypoglycemia, and hypoprothrombinemia. The operation should not be delayed unduly as there is always a danger of further infarction of the bowel, fluid and electrolyte disturbances, and increased risk of infection. In neglected cases with dehydration, more energetic therapy is required.

Sterilization of skin and draping

The use of a neonate-compatible heating mat under the baby or warm air heater is advised. The umbilical cord is cleansed with 70% alcohol and is ligated and transected at the level of the abdominal wall. The operative field is sterilized with

prewarmed povidone–iodine 2% in 70% alcohol. Sterile warm Gamgee rolls or swabs are placed alongside the baby, who is then draped with towels or disposable adherent drapes. A sterile transparent adhesive drape is applied over the operative field to ensure that he/she remains dry during the operative procedure, thus preventing heat loss. Another way of keeping the neonate dry is to place adherent plastic drapes around the operative field prior to skin preparation.

Incision

An adequate incision is required. Exposure is obtained through a supraumbilical transverse incision transecting the rectus muscles 2–3 cm above the umbilicus. The ligamentum teres is subsequently divided and ligated. Alternatively, a small circumumbilical incision may be adequate.[43,44] The circumumbilical incision combines the advantages of an open approach and an abdominal scar which is aesthetically pleasing on healing.[45]

Laparoscopy has been used as an exploratory maneuver in diagnosis with exteriorization of the atretic ends of the bowel through the umbilical port site for primary anastomosis.[46,47]

Exploration

If free gas escapes on opening the peritoneum, or if there is contamination of the peritoneal cavity, a pus swab is obtained for Gram stain and culture, and the site of the perforation is sought and closed before further exploration is carried out. In the presence of peritoneal contamination, the cavity is irrigated with warm saline. The entire bowel is exteriorized to determine the site and type of obstruction and to exclude other areas of atresia or stenosis and associated lesions such as incomplete intestinal rotation or meconium ileus. The appearance of the atretic segment depends upon the type of occlusion, but in all cases, the maximal dilatation of the proximal bowel occurs at the point of obstruction; this segment is often hypoperistaltic and of questionable viability (Figure 58.9), while the bowel distal to the obstruction is collapsed, tiny, and wormlike (Figures 58.5 and 58.6).

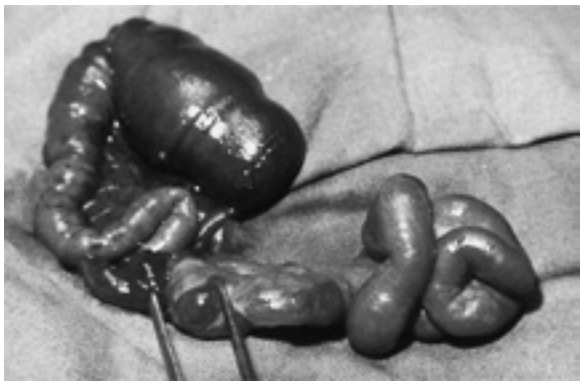

Figure 58.9 The proximal atretic bowel is grossly dilated, hypoperistaltic, and of questionable viability.

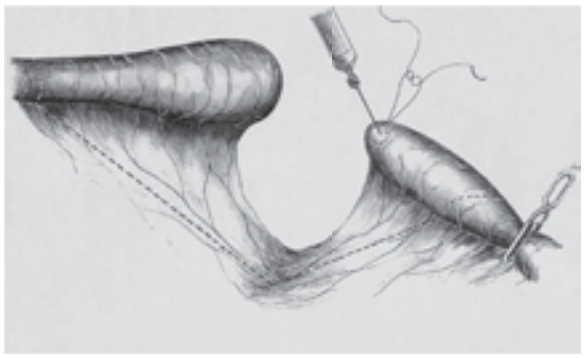

(a)

(b)

Figure 58.10 **(a)** The distal bowel is distended with saline injection proximal to the bowel clamp. The extent of the resection is indicated by the dotted lines. **(b)** The extent of resection in the clinical situation is depicted. Note that all grossly dilated bowel is to be resected.

After the location and type of lesion have been identified, the distal bowel is carefully examined to exclude other atretic segments, which are present in 10%–20% of cases. Saline is instilled into the lumen of the distal bowel to confirm patency. Malrotation is corrected if present. The total length of the small bowel is measured as this has prognostic significance and may determine the method of reconstruction. The normal length of the small bowel at full-term birth is approximately 250 cm.

After complete patency of the distal small bowel and colon has been established, the next task is to suture the disproportionate proximal and distal blind ends. This is facilitated by applying an atraumatic bowel clamp about 6–8 cm from the distal blind end and distending the intervening segment by injection with half-normal saline, taking care not to split the serosa (Figure 58.10a).

Resection

The atretic area and adjacent distended and collapsed bowel are isolated by walling off the rest of the abdominal cavity with moist packs. To ensure adequate postoperative function, the proximal distended and hypertrophied bowel should be liberally resected, even if it appears viable. If the bowel length is adequate (more than 75 cm plus ileocecal valve), the bulbous

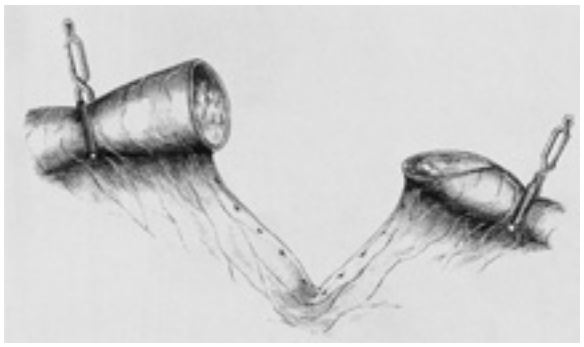

Figure 58.11 The proximal bowel has been transected at right angles and the distal obliquely with continuation of the incision along the antimesenteric border to create a "fish mouth."

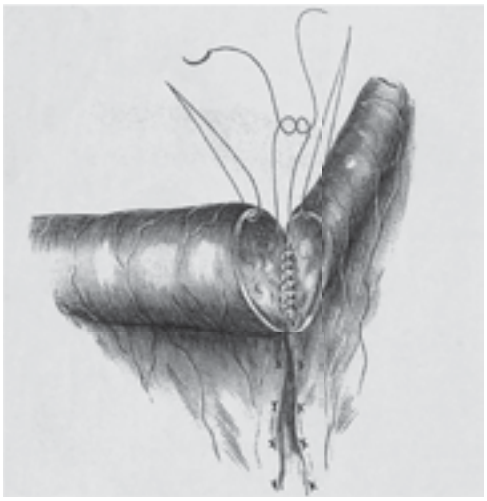
hypertrophied bowel proximal to the atresia is resected to approximately normal bowel diameter; usually, a 10–15 cm section is removed. After milking the intestinal contents into the proximal bulbous end, an atraumatic bowel clamp is applied across the bowel a few centimeters proximal to the site selected for transection. The mesentery adjoining the portion to be resected is divided using bipolar diathermy or ligated up to the proposed lines of section of proximal and distal bowel (Figure 58.10a and b). The blood supply at this point should be excellent, and therefore, the bowel is divided at right angles, leaving an opening of about 1.5 cm in width. Two to three centimeters of the distal bowel is also removed. This bowel may be transected slightly obliquely, and an incision may be continued along the antimesenteric border to create a "fish mouth," which renders the opening about equal to that of the proximal bowel (Figure 58.11). Alternatively, the bowel can be transected at right angles if an end-to-end anastomosis is planned. In patients with a relatively short segment of severely dilated proximal intestine, derotation of the proximal segment, resection to the distal second part of duodenum, and establishment of continuity by end-to-end anastomosis with tapering of the duodenum is a good option. However, in patients with long segments of proximal intestine that are significantly dilated, resection of the whole involved segment may result in inadequate remaining intestinal length to allow absorption of enteric nutrients (i.e., short bowel syndrome). Therefore, these patients frequently are treated by either imbrication or tapering enteroplasty of the proximal dilated segment. In a few cases with extensive congenital short bowel, primary serial transverse enteroplasty procedure (STEP) has been attempted.[48]

Anastomosis

An inverting mattress of 5-0 or 6-0 polydioxanone sutures unites the mesenteric borders of the divided ends, and temporary stay sutures are inserted at the antimesenteric angles to facilitate accurate approximation. The *posterior* edges of the bowel are united with interrupted through-and-through 5-0 or 6-0 polydioxanone sutures tied on the mucosal aspect (Figure 58.12a). The *anterior* edges are joined by similar through-and-through sutures tied on the serosal surface (Figure 58.12b). The completed anastomosis is not strictly end to end but a modification of Denis Browne's "end-to-back" method. An alternative suture technique includes extramucosal anastomosis and the use of 5-0 or 6-0 monofilament absorbable sutures and end-to-end sutures taking larger bites on the proximal bowel. Where there is a discrepancy of less than 4:1 between the proximal and distal bowel lumens, an end-to-end extramucosal anastomosis is advised as there is thought to be an earlier return of normal peristalsis. The suture line is tested for leakage, and reinforcing sutures are inserted as required. The defect in the mesentery is repaired by approximating (and overlapping if necessary) the divided edges with interrupted sutures (Figure 58.12a and b). The intestines are returned to the peritoneal cavity. During this procedure, if the mesentery is kept in the configuration of an open fan (Figure 58.13a and b), kinking or volvulus of the bowel should be avoided.

A similar technique is used for stenosis and intraluminal membranes. Procedures such as transverse enteroplasties, excision of membranes, and bypassing techniques are not



(a)

(b)

Figure 58.12 **(a)** Anastomosis of the posterior wall with interrupted sutures. **(b)** The anterior anastomosis.

recommended, because they fail to remove the abnormal segment of bowel; side-to-side anastomosis is avoided due to the risk of creating blind loops.

Gastrostomy/enteral decompression and early enteral feeding

It was customary in babies with high jejunal atresias just beyond the duodenojejunal flexure to place a transanastomotic feeding tube for early enteral feeding when parenteral feeding techniques were less sophisticated. The tube was passed into the small bowel distal to the anastomosis before completing the anterior layer of sutures and stabilized at the anastomotic site by a single tethering mucosal stitch, in order to prevent its retrograde displacement into the stomach. The transanastomotic tube was passed either via the nasogastric route or via a Stamm gastrostomy performed on the anterior wall of the stomach. More recently, the value of such transanastomotic tubes for feeding has been questioned, and the authors have abandoned routine use of these for high jejunal and duodenal atresias.[49] Placement of a transluminal Silastic tube is, however, a useful maneuver in multiple atresias to align the atretic segments at the time of anastomosis and to provide a transluminal stent in the postoperative period. The tube can be exited via the cecum or through the colon and out the anus.[50] Nutrition is provided by the parenteral route until full enteral feeds are established.

Closure of abdominal wound

Where there has been soiling of the peritoneal cavity from a perforation, the abdominal cavity is again irrigated with saline and all macroscopic debris removed.

The abdominal wound is closed with a single continuous layer of polydioxanone 3-0 or 4-0 sutures to include all layers of the abdominal wall, excluding skin. In fat babies, the adipose layer is approximated with interrupted or continuous 4-0 absorbable sutures. The skin is approximated with continuous subcuticular 5-0 monofilament sutures.

Other surgical maneuvers

In babies in whom the initial insult has resulted in atresias with a markedly reduced length of small intestine or when large resections of multiple atretic segments are required, certain surgical techniques have been advocated in an attempt to preserve maximal intestinal length for survival and growth.[51,52] In addition, disparity in anastomotic size is reduced, and prograde duodenal function is facilitated. In high jejunal atresias, the duodenum is fully derotated and the proximal resection extended into the second part of the duodenum with antimesenteric tapering duodenoplasty or inversion plication of the proximal megaduodenum (Figures 58.14 and 58.15).[53,54] The dilated bowel is trimmed to a lumen size of a 22-French gauge catheter. An intestinal autostapling instrument may be used. Inversion plication without excision and tapering has the advantage of preserving valuable mucosa if the bowel length is short. Tapering may have an advantage over plication, as the latter has the tendency to unravel within a few months with subsequent peristaltic dysfunction, especially if the mucosal strip/excision technique has not been utilized. Following this tailoring, the anastomosis is performed as described earlier, and the bowel is returned to the abdomen in the position of nonrotation. In type IIIb, any restricting bands along the free edge of the distal narrow mesentery are released to avoid kinking and interference with the blood supply. The mesentery from any resected bowel is retained and may assist in closure of mesenteric defects. This technique is very helpful and prevents kinking or distortion of the anastomosis. Furthermore, the potential for kinking the single marginal artery and vein requires careful placement of the bowel into the peritoneal cavity at the completion of the anastomosis.

Although isolated type I atresias are best dealt with by primary resection and anastomosis, multiple diaphragms have successfully been perforated and dilated with bougies

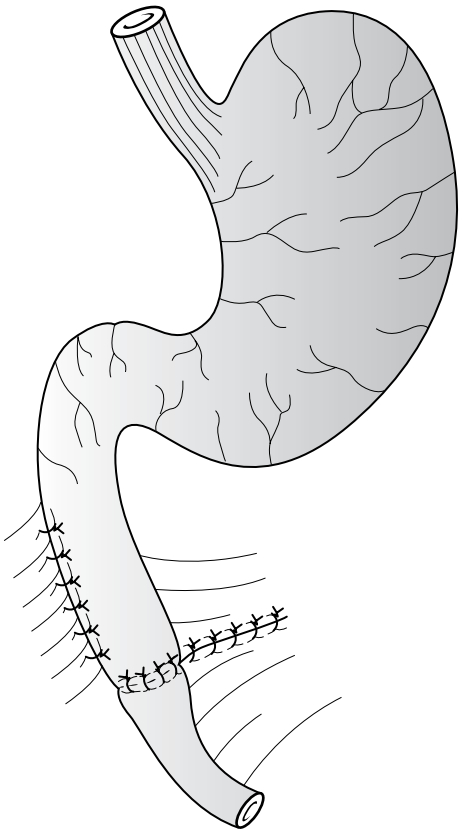

Figure 58.14 The surgical procedure for high jejunal atresia includes: derotation of the bowel, back resection into the second part of the duodenum, tapering duodenoplasty, or linear seromuscular stripping and inversion plication followed by bowel anastomosis.

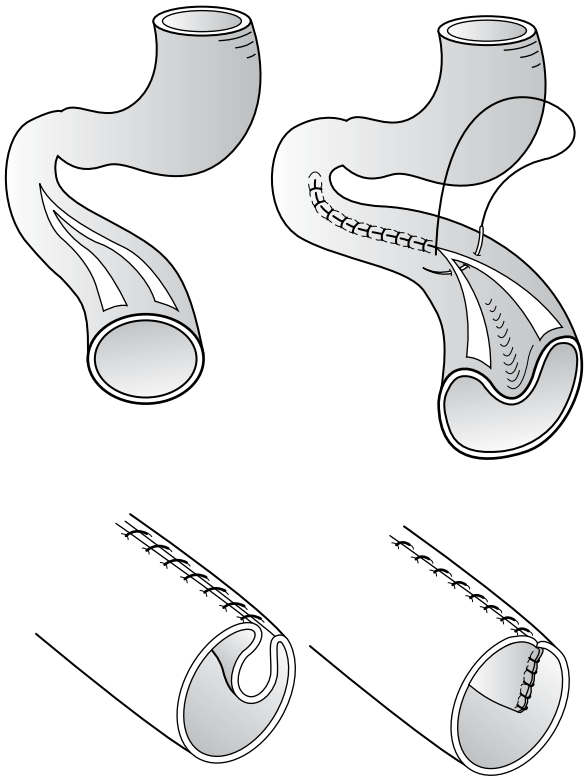

Figure 58.15 The technique of seromuscular stripping and inversion plication. This technique preserves mucosal surface for absorption and prevents unraveling of the placation.

passed along the length of the bowel. In multiple atresias, multiple resections and anastomosis may be advisable to save as much bowel length as possible. They are, however, often localized, requiring resection of all together and a single anastomosis. As mentioned previously, a Silastic tube passed through the lumen of the entire bowel facilitates these anastomotic procedures.[55]

The fashioning of stomas, e.g., Bishop–Koop,[56] Santulli and Blanc,[17] Rehbein,[57] or double barrel,[58] as practiced by some, is not routinely advocated unless there is gross intraperitoneal contamination, making a primary anastomosis unsafe. Jejunoileal atresia associated with a gastroschisis is treated by resection and primary anastomosis only if there is no evidence of edema and matting due to amniotic peritonitis. Initial reduction of the eviscerated bowel with the atresia intact and primary closure of the abdominal wall defect, if possible, is preferred. After allowing for disappearance of the edema (10–14 days), a second laparotomy is performed with resection of the atretic segment and primary anastomosis. Stomas with the potential for fluid and electrolyte loss, wound infection, and other stoma-related complications are thus avoided. There is little place for bowel lengthening procedures at the initial operation. It is advisable to delay such procedures until the neonatal bowel has grown to its maximum potential length and maximum bowel adaptation has occurred.

POSTOPERATIVE CARE

Postoperative care is conducted according to current standards and guidelines. Nasogastric decompression is usually required until proximal gut prograde peristalsis has recovered. High jejunal atresias may require a long period of decompression. Feeding is delayed until the gastric aspirate is no longer bile stained, the abdomen is not distended, and the baby has passed meconium. In babies with a transanastomotic tube, continuous feeding is commenced 24 hours postoperatively. Graduated polymeric feeds are then commenced and increased as tolerated. Oral or gavage feeds are started with return of prograde proximal bowel function.

If at any time, there is a suspicion of a leak at the anastomosis, as suggested by clinical deterioration, abdominal distension, and vomiting, a plain radiograph of the abdomen may reveal free air in the abdomen. When more than 24 hours have elapsed since surgery, this would indicate a leak or perforation, and immediate laparotomy should be performed. Other postoperative complications observed have been ischemia leading to frank necrosis, late-onset stenosis, adhesive obstruction, and perforation of the bowel by the transanastomotic tube. Infants with human

immunodeficiency virus (HIV) exposure or infection have poor healing with an increased incidence of anastomotic breakdown and wound sepsis with dehiscence.[59]

In babies in whom less than 75 cm of small bowel remains, especially if the ileocecal valve is absent, loose frequent stools and excessive water loss may become problematic. In these patients, and in every instance where normal enteral alimentation cannot be established within 5 postoperative days, parenteral feeding is indicated. Solutions containing carbohydrate, amino acid, and fat are introduced in a graduated manner over a period of 3 days. Peripheral venous push-in lines are used for short-term total parenteral nutrition (TPN), but for long-term TPN (longer than 10 days), a central Broviac® line is preferred. Once intestinal function has been reestablished, the baby is gradually weaned from a parenteral to an enteral feeding program. Careful dietary tailoring is required, as each of the patients may have different tolerance thresholds.

Predictions of the degree of intestinal dysfunction are based upon the known residual length of small intestine. Short bowel syndrome can be contemplated if more than 70% of the bowel length was lost or if the minimal bowel length left after surgery is less than 70 cm. These babies can be divided into four main functional groups: (1) those with uncorrectable intestinal insufficiency; (2) those with adequate bowel function for survival after adaptation and/or lengthening and tailoring procedures; (3) those with adequate alimentary function for growth and development; and (4) those with normal alimentary function with a degree of intestinal reserve.

When gross intestinal insufficiency is expected, the infant is managed as short bowel syndrome.[60–62] The patient's oral intake is gradually increased in volume and energy content, while the small intestine is allowed to adapt until maximum intake tolerance is reached, which can take months to years.[63] Pharmacological control of intestinal peristaltic activity has been achieved more effectively since the introduction of loperamide hydrochloride. Vitamin B_{12} and folic acid should be administered to patients without the terminal ileum to prevent megaloblastic anemia. The long-term outcome for most of the babies is optimistic. TPN-associated complications are becoming less frequent, and parenteral nutrition (PN)-associated liver disease can be avoided in most cases, making liver and intestinal transplantation unnecessary.[64]

OUTCOMES

The first successful surgical repair of an intestinal atresia was in 1911.[6] Before 1952, the mortality rate for congenital atresias of the small intestine in Cape Town and in most other centers around the world was 90%. Between 1952 and 1955, 28% of the babies with this condition could be saved. At that stage most were treated by primary anastomosis without resection. With liberal resection of the blind ends and primary end-to-end anastomosis, the survival rate increased to 78% during 1955–58.[65,66]

Improved perioperative care and management of short bowel syndrome, both medical and surgical, has resulted in survival of nearly all cases, except those born with an ultrashort bowel incompatible with enteral autonomy (Figure 58.6c). Most patients with jejunoileal atresias have an excellent prognosis and long-term survival. Those with types III and IV atresias and resultant short bowel syndrome have more feeding problems and a higher morbidity. This increase in survival has come at the cost of a higher percentage of late complications in the surviving children.[67–69]

Associated anomalies may adversely affect outcomes. In predicting the ultimate functional outcome, the following factors must be taken into consideration: the ileum adapts to a greater degree than the jejunum, the neonatal small intestine still has a period of maturation and growth ahead of it, and the actual residual small intestinal length is difficult to determine accurately after birth particularly if the infant is born premature. The proximal obstructed bowel segment is dilated, and its functional potential may be overestimated, while that of the distal unused collapsed bowel may be underestimated. Of critical importance is an intact ileocecal valve, which allows for accelerated intestinal adaptation with shorter residual jejunoileal length. The absence of the ileocecal valve also leads to an increased intestinal content transit time, malabsorption, diarrhea, and increased bacterial contamination of the small bowel.

During the 25-year period from 1990 to 2015, 160 patients with jejunoileal atresias and stenoses were admitted to the pediatric surgical service at the Red Cross War Memorial Children's Hospital. There were 13 deaths (92% survival). Factors contributing to the mortality rate were as follows: type of atresia (type III, 32%), proximal bowel infarction with peritonitis, anastomotic leak with a missed distal atresia, atresia associated with gastroschisis, ultrashort bowel syndrome with PN-associated liver disease, sepsis, and more recently, HIV infections. Overall experience is recorded in Table 58.1.

Colonic and rectal atresias

TOMAS WESTER

COLONIC ATRESIA

Introduction

Binninger was the first to describe colonic atresia in 1673.[1] The first survivor was reported in 1922, when Gaub[2] opened a diverting colostomy in a child with an atresia of the sigmoid colon. Potts[3] successfully performed a primary anastomosis in a neonate with an atresia of the transverse colon in 1947.

Atresia of the colon is a rare cause of bowel obstruction in the neonate. The incidence of colonic atresia in live births has been difficult to ascertain, but an incidence of approximately 1 in 20,000 live births has been considered to be realistic based on the experience in major pediatric surgical centers.[4] In the northwest of England, isolated colonic atresia has been reported to occur in 1 in 66,000 live births.[5] Other investigators have reported that colonic atresias account for 1.8%–10.5% of the total bowel atresias,[6,7] the incidence of which has been estimated to be 1 in 1500 to 1 in 20,000 live births.[1,8] Colonic stenosis is extremely rare.

Except for stenosis, three different types of intrinsic occlusion have been distinguished:[9,10]

1. Type I atresia or a membrane (Figure 59.1a)
2. Type II atresia with blind ends of bowel joined together by a cord-like remnant of bowel, with or without a gap in the mesentery (Figure 59.1b)
3. Type III atresia with separated blind ends of bowel and a gap in the mesentery (Figure 59.1c)

Furthermore, a hereditary form with multiple atresias of the gastrointestinal tract has been described, suggested to be of nonvascular origin.[11,12] Type III atresia appears to be the most common type proximal to the splenic flexure, whereas types I and II are more common in atresias distal to the splenic flexure.[13,14] In a literature review, it was reported that type III occurred in 60.4% of all cases.[15] Most series show an even distribution between atresias proximal and distal to the splenic flexure.[6,7,16,17]

Etiology

Colonic atresia is probably the result of intrauterine vascular insufficiency. The finding of bile, squamous epithelium, and hair in the bowel distal to the atresia supports the hypothesis that the vascular accident occurs late in development.[9] Several pathological conditions may result in compromised blood supply to the bowel, such as intussusception, volvulus, herniation, tight gastroschisis, and embolic or thrombotic events. It appears likely that focal resorption of the sterile gut occurs after ischemic necrosis. Animal experiments have been performed in which the blood supply was interrupted to different parts of the small intestine or colon, thus inducing various types of atresias. These experiments confirm the etiologic role of *in utero* vascular occlusion.[9,18,19]

Colonic atresia has been reported in monozygotic twins.[20] Benawra et al.[21] reported three cases occurring in first-degree relatives of a family. Fairbanks et al.[22] have shown that absence of fibroblast growth factor 10 (*Fgf10*) or its receptor fibroblast growth factor receptor 2b (*Fgfr2b*) results in colonic atresia in a mouse model, despite normal mesenteric vascular development. These findings suggest that genetic factors may play a role in the pathogenesis of colonic atresia.

Presentation

Neonates with colonic atresia present with symptoms of distal bowel obstruction. Abdominal distension is usually present at birth, but otherwise develops over the first 24–48 hours of life. Bile-stained vomiting is very common, but is not always an early symptom. Failure to pass meconium is the rule, and neonates that do not pass meconium within the first 24 hours of life should be considered for further investigations. On examination, the abdomen is distended and often slightly tender, sometimes with visible bowel loops. In those who have an abdominal wall defect, associated atresias should always be suspected.

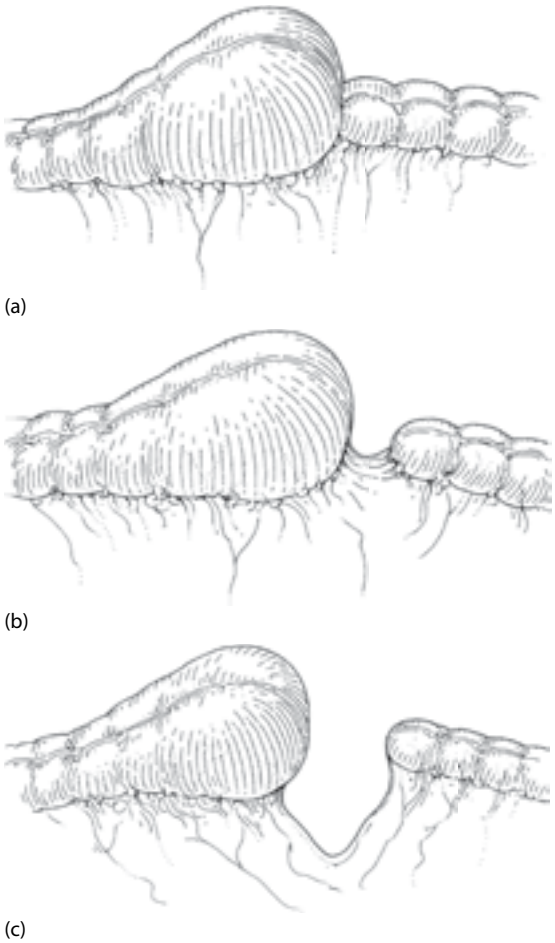

Figure 59.1 **(a)** Type 1: there is continuity of the outer layers of the bowel wall; the lumen is obstructed by a membrane covered with two layers of mucosa. **(b)** Type II: the bowel ends are connected by a fibrous band and the mesentery is intact. **(c)** Type III: a defect in the mesentery is accompanied by a gap between the bowel ends. (Reprinted from Wester T. Colonic and rectal atresias. In Puri P (ed). *Newborn Surgery*, 3rd edn. London: Hodder Arnold, 2011: 505–11, Figure 53.1. With permission.)

Colonic atresia is associated with abdominal wall defects, such as gastroschisis, cloacal exstrophy, and more rarely omphalocele, which complicates the management of these patients.[4,14] Boles et al.[14] found that 4 of their 11 patients had gastroschisis. In the series reported by Philippart,[4] 22 of 36 patients with colonic atresia had no associated anomalies, whereas 6 had cloacal exstrophy, and 3 had other abdominal wall defects; 5 of the 36 patients had jejunal atresia associated with the colonic atresia. Rarely, colonic atresia has been reported to occur concomitantly with imperforate anus.[7] Malrotation has also been reported to be a common associated anomaly.[15] One important associated anomaly is Hirschsprung's disease, which has been reported in a few cases. Although the colonic atresia was diagnosed at birth in these patients, there was a considerable delay in diagnosing the associated aganglionosis. It is therefore recommended that resected bowel is examined for Hirschsprung's disease.[23] Rectal suction biopsies are suggested in patients that do not gain normal bowel function postoperatively.[24] Some authors recommend that rectal suction biopsies should be routinely taken in all patients with colonic atresia.[15,25] Isolated colonic atresia is sometimes associated with skeletal anomalies such as syndactyly, polydactyly, absent radius, and clubfoot.[4] Furthermore, colonic atresia has been reported in association with eye anomalies, such as exophthalmos and optic nerve hypoplasia.[13] In the series reported by Davenport et al.,[5] one patient had trisomy 18 and esophageal atresia. The fact that chromosomal abnormalities do occur in patients with colonic atresia makes it reasonable to recommend chromosomal analysis, at least in those patients who have other associated anomalies.

Diagnosis

Prenatal diagnosis of colonic atresia has been reported. However, prenatally detected colonic dilatation may also be the result of Hirschsprung's disease or anorectal malformations.[26]

Plain radiographs show a distal bowel obstruction with multiple dilated loops with air-fluid levels. A large right-sided loop, corresponding to the proximal dilated colon, has been considered characteristic in patients with colonic atresia (Figure 59.2a).[5] The level of obstruction is confirmed by a contrast enema, which reveals the distal microcolon and incomplete filling of the colon (Figure 59.2b). Pneumoperitoneum, indicating colonic perforation, is not rare and has been reported in approximately 10% of the cases.[4]

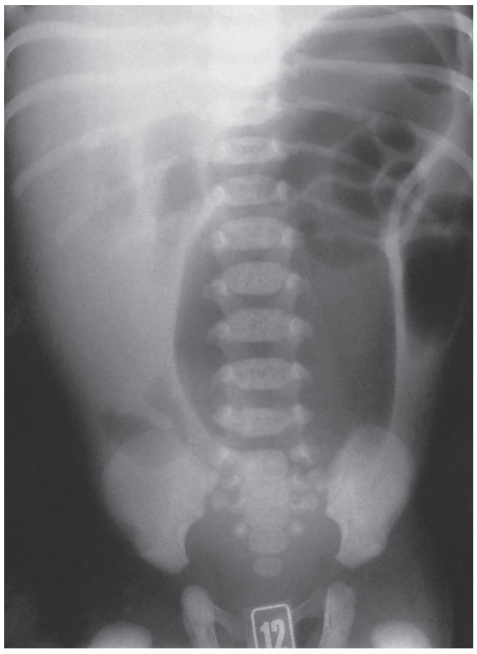
Management

PREOPERATIVE

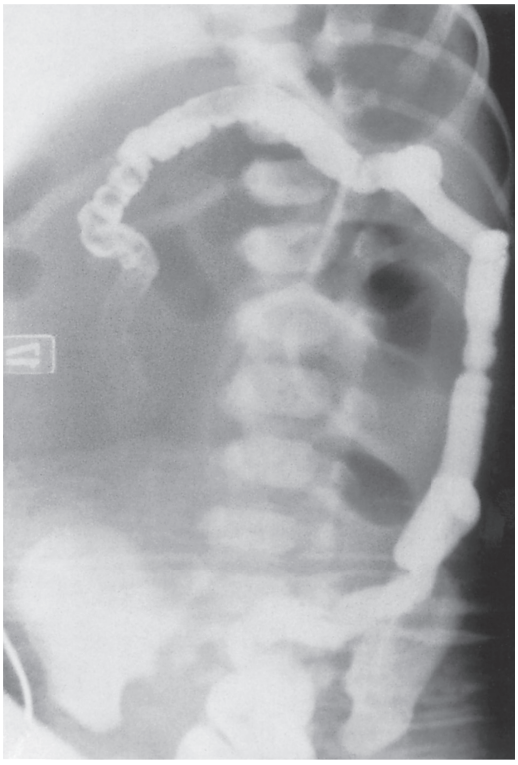
Correction of fluid and electrolyte abnormalities is started as soon as bowel obstruction is suspected. The gastrointestinal tract is decompressed with a nasogastric tube. Prophylactic antibiotics are administered. The neonate should be in a stable condition before general anesthesia and the operation are started.

OPERATIVE

The two therapeutic options available are primary resection with anastomosis and colostomy with anastomosis at a later stage. Traditionally, many authors distinguished between the management of colonic atresia distal and proximal to the splenic flexure. Atresias proximal to the splenic flexure were treated with primary resection and anastomosis, whereas the distal atresias were treated with primary colostomy and delayed establishment of the gastrointestinal continuity.[4,7,13,17,27] More recently, it has been suggested that staged repair should be undertaken in complex cases with, for instance, questionable bowel viability, colonic perforation and peritonitis, and in patients with concomitant abdominal wall defects. On the other hand, in uncomplicated cases, resection and primary anastomosis has been proposed to be the method of choice for atresias at all levels of the colon.[28] There is no evidence that this later approach



(a)



(b)

Figure 59.2 **(a)** Plain abdominal radiographs often show the hugely dilated bowel segment proximal to the atresia. **(b)** Contrast enema is diagnostic of a colonic atresia showing a microcolon and incomplete colonic filling.

increases the mortality or complication rate,[5,29] although the anastomosis may be technically difficult because of the large discrepancy between the diameters of the proximal and distal bowel.[30] England et al.[31] reported that a temporising stoma does not reduce the diameter of proximal bowel

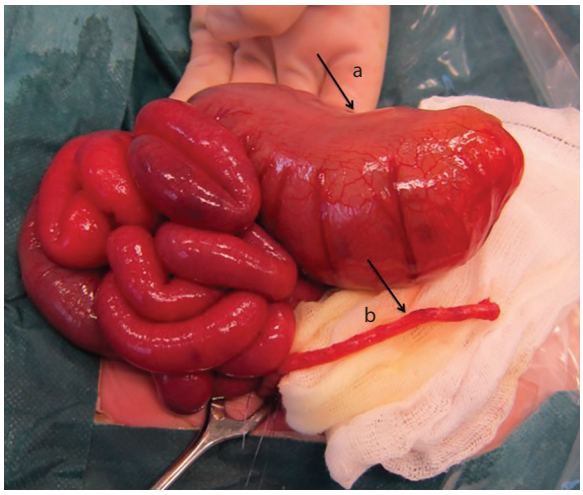


Figure 59.3 Proximal colon is hugely dilated (arrow **a**), while the distal colon is very small (arrow **b**).

and therefore recommended right hemicolectomy and primary anastomosis for proximal colonic atresia.

The abdomen is opened through a transverse incision a finger diameter above the umbilicus and to the right. The incision may be extended as required. Cautery is used to divide the muscle layers of the abdominal wall, and the umbilical vein is ligated and divided. The site and type of atresia are assessed (Figure 59.3). It is extremely important that additional atresias are excluded. The patency of the distal colon must always be tested by, for instance, injection of saline. In those with type I atresia, the bowel adjacent to the atresia is resected, and a primary anastomosis is performed. In patients with types II and III atresias, with adequate bowel length, the excessively dilated proximal bowel should also be resected (Figure 59.4a). A few centimeters of the distal narrow bowel are resected. The mesenteric vessels are divided close to the bowel wall to preserve the blood supply to the adjacent bowel. The distal bowel is incised along the antimesenteric border to achieve lumina of a similar diameter (Figure 59.4b). A single-layer anastomosis is performed using interrupted 5-0 absorbable sutures (Figure 59.5a–c). The wound is closed in layers with absorbable sutures.

POSTOPERATIVE

During the first postoperative days, parenteral nutrition is administered. Feeding can be started when the baby is well and the gastric aspirates have decreased. In cases with a primary anastomosis, it usually takes a few days before the neonate starts to pass stools. If a colostomy has been fashioned, the parents are instructed how to take care of the stoma. Usually the colostomy is closed at 2–3 months of age.

Complications and long-term results

Many factors have led to an improvement in the results of patients with colonic atresia, including early postnatal diagnosis, improved neonatal intensive care and anesthesia, and

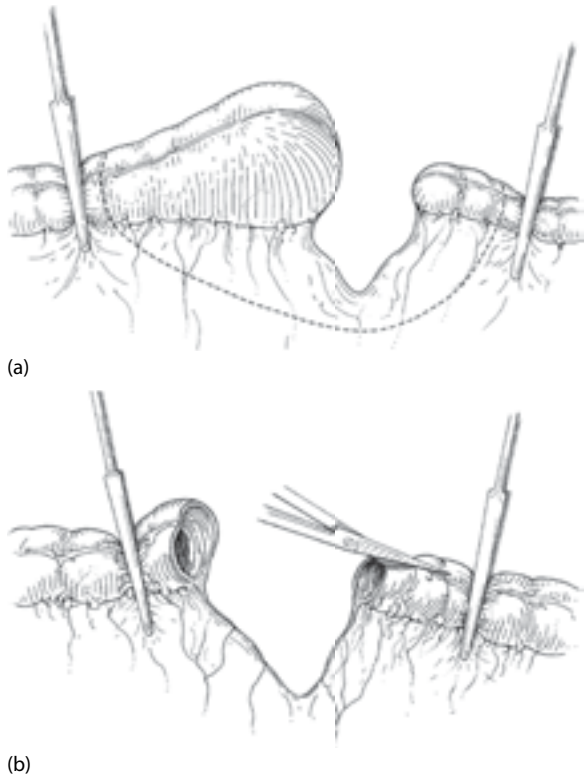

Figure 59.4 **(a)** Dilated proximal and the relatively ischemic portion of colon just distal to the atresia are resected. **(b)** Distal colon is incised along its antimesenteric border to match the luminal diameters of the two portions of bowel to be joined. more efficient transport facilities. Today, mortality related to the colonic atresia or its treatment is rare. In the series reported by Davenport et al.,[5] no deaths occurred in the patients that underwent surgery, although one patient, who was never operated on, died of associated abnormalities. The mortality rate in earlier series varied from 9% to 33%, in many cases as a result of associated anomalies, but also attributable to late diagnosis, nutritional deficiencies, infectious complications, and technical errors.[6,7,13,14,17] Etensel et al.[15] recently reported a lethal outcome in 27% of the cases collected for a literature review.

Powell and Raffensperger[13] reported 15 postoperative complications in 19 patients. Problems related to the colostomy were encountered in 3 of 11 patients treated with colostomy and delayed anastomosis, whereas anastomotic strictures were seen in 6 of the 19 patients. Boles et al.[14] reported significant complications in 4 of 11 cases. The use of contemporary principles of neonatal surgery has, however, reduced the morbidity rate, and Davenport et al.[5] reported recovery without complications.

RECTAL ATRESIA

Introduction

Rectal atresia is a very rare lesion, which has been reported to account for 0.3%–1.2% of all anorectal malformations.[32–34] Interestingly, a much higher incidence of 14% has been reported from Tamil Nadu in the southern part of India.[35] The reason for this high incidence has been poorly understood. However, in recent years, the incidence in Tamil Nadu has been reduced and is now similar to that in other parts of the world.

Although it has been proposed that rectal atresia should be classified as a colonic atresia,[6] it is usually considered to be part of the spectrum of anorectal malformations. Rectal atresia was classified as a type IV anomaly in the Ladd and Gross classification of anorectal anomalies.[36] In the international classification and the Wingspread classification, it was also classified as a separate type of high anomaly.[37,38] Peña's[39] classification describes rectal atresia as a separate entity, while the more recent Krickenbeck classification describes rectal atresia/stenosis among rare or regional variants of anorectal malformations.[40] Five types of rectal atresia have been distinguished: type 1 with a membrane

and intact bowel wall; type 2 with blind ends separated by less than 2 cm, which is the most commonly encountered type; type 3 with a long distance between the blind ends; type 4, which is rectal stenosis; and type 5 with a urinary fistula accompanying the rectal atresia (Figure 59.6).[41]

Etiology

Magnus[42] described the autopsy findings in a female neonate with multiple atresias of the small and large bowel, including a rectal atresia. It was found that there were intact remnants of the internal sphincter, that the epithelium of the anal canal was normally developed, and that the external sphincters were normal (Figure 59.5). There was a fibromuscular band between the blind rectal pouch and the anal canal. Based on the findings in the autopsy specimen, the author suggested that rectal atresia is the result of vascular insufficiency, rather than a developmental defect. It was speculated that this could be the result of an intrauterine infection. It was also estimated that the lesion occurred between the 65 and 112 mm stages of development. Dorairajan[35] has suggested that the middle rectal artery is involved, rather than the superior rectal artery, which has been proposed by other investigators.

Presentation

Neonates with rectal atresia present with distal bowel obstruction comprising abdominal distension and failure to pass meconium. The perineum and anal canal are normal, and the diagnosis may therefore easily be delayed. The atresia is usually located 1–3 cm above the dentate line.

The incidence of associated anomalies in patients with rectal atresia has been considered to be extremely low.[43] In the series reported by Dorairajan,[35] associated anomalies were found in 2% of the 147 cases. No significant abnormalities were found in the urinary tract. Patients with rectal atresia usually have a normal perineum and a normal sacrum. Rectal atresia occurs in patients with multiple atresias of the bowel.[42] Two of Dorairajan's[35] patients had ileal atresia, and one had multiple small bowel atresias. Patients with rectal atresia and particularly rectal stenosis may have an associated presacral mass, and it has been recommended that they should undergo MRI like other patients with anorectal malformations.

Diagnosis

The condition is diagnosed when an attempt is made to pass a thermometer or a tube to decompress the colon. After a colostomy has been opened, a contrast study with simultaneous injection of contrast material through the colostomy into the rectal pouch and the anal canal clearly outlines the anatomy of the anomaly (Figure 59.7).

Management

In the past, several different techniques, such as abdominoperineal and sacroperineal pull-through procedures, referred to by Stephens and Smith[44] and de Vries et al.[45] were used to treat rectal atresia. More recently, other methods have been described. Gauderer and Izant[46] placed a string across the membrane using fluoroscopy and progressively

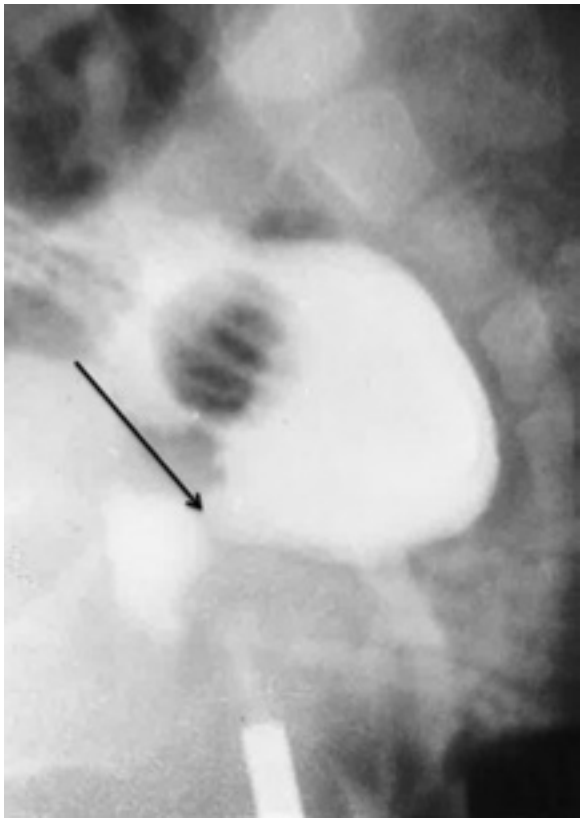

Figure 59.7 Simultaneous injection of contrast material into the upper pouch (via the sigmoid colostomy) and the anorectum clearly outlines the distance between the two pouches. The arrow shows the atresia.

dilated the rectal canal in one patient. Zia-ul-Miraj Ahmed et al.[47] used a Duhamel procedure in seven cases with rectal atresia and rectal stenosis. Dorairajan[35] fashioned a transverse colostomy in the newborn and did a definitive sacroperineal pull-through operation at approximately 1 year of age. If the blind rectal pouch ended above the pubococcygeal line, a sacro-abdomino-perineal or an abdominoperineal approach was preferred. The colostomy was closed in a third stage. Upadhyaya[41] recommended transanal end-to-end rectorectal anastomosis. One advantage of this technique is that luminal continuity is restored without injuring the functional anatomy of the region. A sigmoid colostomy is opened in the neonate, and the definitive procedure is performed at approximately 3 months of age. A Hegar dilator is advanced distally from the colostomy until it pushes the rectal pouch into the anal canal. The end of the anal canal is opened and the margins retracted with stay sutures. Then the rectal pouch is opened, and the edges of the anal canal and the rectal pouch are approximated to form an end-to-end anastomosis.[48] A similar technique, using an endoscope instead of a Hegar dilator, was recently described.[49] Transanal pull-through with mucosectomy, similar to the procedure used for Hirschsprung's disease, has been suggested also for rectal atresia.[50,51] Nguyen and Pham[52] used a combined laparoscopic and transanal approach.

Peña and DeVries[53] suggested that posterior sagittal anorectoplasty is a useful method for the repair of rectal atresia and stenosis. It is recommended that a diverting colostomy is opened in the newborn, and the definitive procedure is performed at a later stage.[39] A midline skin incision is performed, and the levator muscle and muscle complex are separated exactly at the midline to expose the bowel. The blind end of the rectum is usually separated from the anal canal with a few millimeters of fibrous tissue. The rectum has to be mobilized to allow an end-to-end anastomosis to be performed without tension. More recently, a technique sparing the anterior dentate line was introduced.[54] The wound is closed by reconstruction of the muscle structures. Daily dilatations are performed starting 2 weeks postoperatively. The colostomy is closed approximately 3 months after the operation, provided the diameter of the anastomosis is appropriate.[53]

In utero repair of rectal atresia was recently reported in a fetus that also had a sacrococcygeal teratoma.[55]

Complications and long-term results

In patients with rectal atresia, the anal canal, sacrum, and sphincteric mechanisms are virtually normal. Therefore, the prognosis with respect to functional outcome is favorable. Although the number of cases reported is very limited, the outcome in patients with rectal atresia or stenosis treated through a posterior sagittal approach is excellent. Peña[39] reported voluntary bowel movements with total continence and without soiling in a series of five cases. However, two of the five patients had constipation. The same group showed, in a more recent series of 17 patients, that all 12 patients older than 3 years had voluntary bowel movements and were clean between bowel movements; 5 (29%) of the 17 patients had constipation that required laxatives. The authors report that complications occurred in three patients: one rectovaginal fistula and two presacral abscesses.[54] Constipation has been reported to occur frequently after other procedures were used to treat rectal atresia or stenosis as well.[47] Upadhyaya[48] reported an uneventful recovery and normal continence in two patients treated with his method. Dorairajan[35] was able to follow up 37 of 60 patients that were treated with sacroperineal pull-through operations and who had their colostomy closed. The outcome was excellent in 20% of the patients, whereas 65% had occasional soiling at night and 15% had soiling also in daytime. The mortality rate in this series was 35%.

CONCLUSION AND FUTURE DIRECTIONS

Colonic and rectal atresias are both very rare conditions. The long-term results appear to be good, although there are limited data on the outcome in adulthood in patients with colonic and rectal atresia. For colonic atresia, the surgical options are mainly resection and primary anastomosis or colostomy with delayed anastomosis. For rectal atresias, several techniques have been described. There is little evidence to show that one technique is better than the other. It is, also with multicenter studies, difficult to get a sample size that is large enough to compare the methods.

Meconium ileus

GUIDO CIPRANDI AND MASSIMO RIVOSECCHI

DEFINITION

Meconium ileus is an early manifestation of cystic fibrosis (CF), due to abnormal, inspissated, and viscid mucus of intestinal origin. In children affected by this condition, the impacted meconium produces an intraluminal obstruction occurring in the midileum, leading to a progressive distension. As an ultimate evolution, different mechanical complications can be associated, including intestinal volvulus, atresia, gangrene and necrosis, perforation, peritonitis with abdominal calcifications, and finally, meconial pseudocyst. In this view, meconium diseases in infancy cannot be firmly separated into three categories, such as meconium plug syndrome, meconium ileus, and meconium peritonitis, nor can therapy of each condition.

HISTORICAL DATA

Intestinal occlusion, associated with both inspissated meconium and gross pathologic pancreatic changes, was first reported by Landsteiner[1] in 1905 and subsequently confirmed by Kornblith and Otani[2] and Fanconi et al.,[3] who correlated chronic lung disease and pancreatic insufficiency. In 1936, Fanconi et al. described this complex and lethal newborn condition as a "cystic fibrosis of the pancreas."

In the middle of the century, Bodian's[4] intuition of an abnormal sticky intestinal mucus, with a lower content of water, provided the basis for a modern treatment with intraoperative saline irrigations, thus avoiding undue small bowel resections. Mikulicz, Gross, Bishop and Koop, Santulli, and others were responsible, in those years, for different surgical techniques including distal or proximal enterostomies.[5] More recently, Noblett[6] and Shaw[7] reported relief of intestinal obstruction by irrigating with various solutions as well normal saline, 1% *N*-acetylcysteine, hyperosmolar gastrografin enema, surfactant, and DNase. With respect to different types of surgical and medical efforts, the survival rate at 1 year increased from 10% to 90%, and the operative mortality drastically decreased to 15%–23% of treated newborns.[8]

INCIDENCE

Meconium ileus accounts for 9%–33% of all neonatal intestinal obstructions (300 new cases in Italy each year) and could be defined as the third most common cause of neonatal small bowel obstruction after ileal and duodenojejunal atresia and malrotation.[9]

It is more frequently observed in predominantly white countries, where the presence of CF is higher, ranging from 1 in 1200 to 1 in 2700 live births. On the contrary, the disease is nearly absent in some Asian peoples and in black Africans. Although meconium ileus can rarely occur in otherwise normal patients, the majority of children affected by this condition have CF. The mean incidence of meconium ileus in CF is at least 18%, with no difference between sexes: when this association coexists, meconium ileus is the presenting symptom in 12% of these children.[10] In contrast to this pathology, meconium plug syndrome is more commonly seen in premature infants, is characterized by colonic obstruction, and is infrequently associated with CF.[11] Approximately half of neonates with meconium ileus present with complicated intestinal obstruction and they always require a surgical procedure. In contrast, only 6%–10% of uncomplicated forms fail nonoperative management using a water-soluble contrast enema: these patients are candidates for a temporary diversion or a major procedure.[12,13]

PATHOGENESIS

Meconium ileus is an essential expression of CF, which is the most common lethal autosomal recessive disorder in white populations, and is characterized by dysfunctional chloride ion transport across epithelial surfaces. Parents are not affected, but both are heterozygotes carrying the abnormal gene(s). The intestine, pancreas, lungs, sweat glands, liver, and salivary glands are all involved, as a result of abnormal exocrine gland activity. However, these organs will be differently affected during life, the pancreas being the first, because the progressive retention of secretions and the atrophy of the acinar cells start during fetal life; in contrast, the lungs are

normal at birth, and the mucus plugging of the distal airways will be responsible for progressive pulmonary insufficiency during adolescence. Meconium ileus is a rare expression of CF in premature infants, suggesting that the intestinal abnormalities take place during the last period of the fetal life.

Although recurrent lung infections and pulmonary insufficiency are the principal causes of morbidity and death, gastrointestinal signs and symptoms commonly precede the pulmonary findings and may suggest the diagnosis in infants and young children. The gastrointestinal manifestations of CF result primarily from abnormally viscous luminal secretions within hollow viscera and the ducts of solid organs. As a result, bowel obstruction may be present at birth due to meconium plug syndrome or meconium ileus. The first biochemical studies of the altered meconium showed a lower content of carbohydrate, more proteins, and more so-called mucoproteins and albumin, which have been used as a screening test in years prior. Meconium ileus more recently appeared as a result of abnormal intestinal secretions, but not so closely related to the sweat electrolyte defect (high levels of sodium and chloride): in fact, the impermeability of CF epithelia to chloride ions is not correlated to the severity of intestinal involvement, and the pancreatic lesions plays a secondary role. Actually, the sweat test is the main laboratory test used for the diagnosis, but after the 1990s, genetic analysis commonly has been used for diagnostic as well as prognostic purposes.

From a genetic point of view, the cystic fibrosis transmembrane conductance regulator (CFTR) is the gene product defective in CF; it was first identified in 1989.

The CFTR gene is normally located in the apical membrane of the epithelial cells from the stomach to the colon: a mutation of CFTR on chromosome 7 is responsible for evidence of CF. The most common mutation is ΔF-508 and can be identified using DNA testing in affected neonates as well as in family members, possible carriers of the specific gene.

The CFTR gene codes for a 1480-amino-acid protein that acts as a chloride channel, regulated by cyclic AMP. In the small intestinal wall, the clinical expression of CF depends largely on the decreased secretion of fluid and chloride ions, the increased permeability of the paracellular space between adjacent enterocytes and the sticky mucous cover over the enterocytes. As a rule, brush border enzyme activities are normal, and there's some enhanced active transport as shown for glucose and alanine. As a result, the gastrointestinal content in children affected by meconium ileus differs mainly from the normal condition by the lower acidity in the foregut and the accretion of mucins and proteins, resulting in intestinal obstruction in the ileum but also in the colon. During growth, the small intestinal mucosa won't be functioning at maximal capacity. Better understanding of the CF gastrointestinal phenotype may contribute to improvement of the overall well-being of these first-seen newborn patients. In the recent years, the Na^+-dependent amino acid transporter called ATB(0), which has been previously localized in the 19q13.3 region, did not appear to be associated with cystic fibrosis-meconium ileus (CF-MI) disease; however, fine chromosomal mapping of other genetic factors and loci, in human as well as animal models, such as the mouse, could be useful in determining the association with the intestinal phenotype of CF. We assume that this work will be very hard because more than 1000 mutations have been identified in the CFTR gene and the final impact of these mutations on the genotype–phenotype correlation is actually unknown. In addition, the discordant phenotype observed in CF siblings suggests that genes other than CFTR modulate the CF phenotype.[14–16]

HISTOPATHOLOGY

In meconium ileus, the intestine shows different aspects if we consider the *proximal*, the *middle*, and the *distal* ileum. In the first portion, a nearly normal evidence is present, with a progressive dilatation at the midportion borderline. In the proximal ileum, the content has a semiliquid consistency and is not yet viscous. A marked and severe dilatation of the middle ileum is ever seen: the intestine contains thick, dark green, and puttylike meconium, firmly adherent to the walls. The intestinal obstruction causing hyperperistalsis is responsible for the congestion and hypertrophy of the walls. The distal ileum is full of concretions called "rabbit pellets," gray stained and with a beaded typical appearance. This condition of the small bowel is responsible for a narrow, empty, and small colon, never used, which is called *microcolon*.[17]

When meconium ileus is complicated, more severe aspects can be seen: the dilatation is responsible for wall perforation and for secondary meconium peritonitis, with calcifications. The spontaneous healing of the ileal perforation could lead to resorption of the involved portion of bowel and finally, to an intestinal atresia. When the peristalsis is vigorous, the twisting of the ileal tract full of dense meconium may result in a massive volvulus, with a high risk of perforation. Sometimes, when the bowel perforation is massive, an intense reaction to the meconial spillage may produce a giant meconial pseudocyst. Obviously, a postnatal perforative evolution of meconium ileus is complication by bacterial peritonitis.

CLINICAL PICTURE

Polyhydramnios is the most frequent feature observed in prenatal diagnosis of complicated forms of meconium ileus. The presence of fetal hyperechogenic bowel on the ultrasound (US), associated with dilated bowel and/or ascites, could be indicative of an intestinal obstruction. A family history of CF is clearly evident in almost 25% of these patients. Meconium ileus is uncommon in premature infants (5%–12%), and associated congenital anomalies are rare.[18]

Main symptoms include abdominal distension (96%), bilious vomiting (50%), and delayed passage of meconium (36%). From a clinical point of view, it is possible to recognize two different conditions: a simple, uncomplicated, and nonsurgical type, and a complicated, severe type, with a mortality of at least 25% of all cases. In the first type

(58%), signs and symptoms of a distal ileal obstruction are seen not later than 48 hours after birth: generalized abdominal distension with dilated and visible as well as palpable loops of bowel, bilious vomiting, no stools, and narrowing of the anus and rectum, with only a dense and rubberlike gray meconium sticking to the anal wall. In the second type (42%), the neonate represents a surgical emergency that must be treated within 24 hours before birth, when the signs of hypovolemic shock or sepsis are not well established. Fetuses with complex meconium ileus are at increased risk for postnatal bowel obstruction and perforation.[19]

In this serious illness, the progressive abdominal distension may culminate in a respiratory distress. If a perforation occurs, pneumoperitoneum and sepsis are the unfavorable consequences. Infrequently, meconium in the vagina or scrotum is evidence of a fetal perforation. Sometimes, the onset is directly with a meconium peritonitis, which could involute to a giant meconial pseudocyst: when this happens, abdominal skin edema and translucency are evident and associated with a palpable right lower mass.

At present, whatever is the clinical presentation picture, the overall survival rate is at least 95%.[20]

PRENATAL US AND RADIOLOGIC PATTERN

Meconium usually fills the small bowel during the 20th week of gestation, so identification of meconium ileus before this period is rare. Prenatal US has led to confidence in the antenatal diagnosis of intestinal obstruction, allowing counseling and birth planning. In this regard, the presence of fetal hyperechogenic bowel on US, associated with dilated bowel and/or ascites, could be indicative of an intestinal obstruction. The increased echogenicity of the intestinal loops is due to a higher density of the intraluminal content (hyperdense and dry meconium). However, it is not easy to determine exactly if this feature is arising from intraluminal or extraluminal structures, and other different condition may present with similar US pattern, such as prenatal infections, neoplasm, or chromosomal trisomy. In addition, these findings may also represent transient normal variants According to final US findings in utero, patients can be classified into three types: type I (massive meconium ascites), type II (giant pseudocyst), and type III (calcification and/or small pseudocyst). This classification may be useful for perinatal management of complicated meconium ileus.[21]

The cystic or pseudocystic type of meconium peritonitis may have a potentially rapid lethal course, and the onset of fetal anemia and polyhydramnios is a bad prognostic factor. Severe evolution in hydrops and fetal distress may occur at any moment, suggesting the persistence of a leakage or rerupture of the cysts with new meconium spillage into the abdomen.

Postnatal radiological imaging does not offer further information over prenatal imaging, and surgical decision should not be influenced by the absence of abdominal free air. Urgent abdominal drainage at birth, followed by intestinal diversion of persistent intestinal perforation on the first day of life, may prevent bacterial colonization and improve prognosis.[18,22]

When meconium ileus evolves into a volvulus, the US shows enlarged hyperechogenic loops without peristalsis. Polyhydramnios is the most frequent feature observed in prenatal diagnosis of complicated forms of meconium ileus.

Obviously, if the parents are found to be carriers for a CF mutation, the correlation between US findings and meconium ileus is done.

Plain radiographs show distended and gas-filled intestinal loops. Sometimes, air–fluid levels are seen (one-third of the cases), thus mimicking an ileal atresia. Where a sharp stop image is evident, this is the exact point of the obstruction. A usual image of fine, granular soap-bubble (Singleton sign) or ground-glass appearance (Neuhauser sign) is due to a dense meconium mixed with air, typical of the distal ileum: this picture is usually located in the midabdomen or in the right iliac fossa. Nevertheless, this image has also been observed in neonates with meconium plug syndrome, Hirschsprung disease, or small bowel atresia. The meconium hyperdensity may produce various images, depending from the length or the localization of the obstructed bowel, but also on the filling (complete or partial) of the intestinal loops affected. When meconium ileus is complicated, the abdominal radiograph may show calcification as a result of meconium peritonitis due to a fetal perforation of the intestine. A double-bubble image or air–fluid levels can be seen when a secondary ileal atresia (single or double) is the final bowel remodeling after a complete volvulus associated with a severe ischemic damage. If the intestinal perforation occurs early in the antenatal period, the x-ray appearance of a round rim of calcification underlines a meconium pseudocyst. The colon is always a microcolon (unused colon) because the meconium never fills the large bowel during fetal life. So, the length is normal, but the caliber is small because of a small amount of feces (thick and dry meconium) passing through.

A water-soluble contrast enema is useful for both diagnostic and therapeutic purposes: the iso-osmolar agents facilitate evacuation of meconium without loss of large amounts of fluids and solutes.

DIAGNOSTIC CRITERIA AND DIFFERENTIAL DIAGNOSIS

The sweat test provides a quantitative estimate of sodium and chloride in a collected sample of sweat, usually from the forearm. A cholinergic drug acts by stimulating sweat production with the help of a mild electrical current applied for 3–6 minutes (pilocarpine iontophoresis technique). Concentrations of these two cations above 60 mEq/L are diagnostic if at least 100 mg of sweat is collected. However, in the early neonatal age, it is really difficult to obtain a sufficient quantity of sweat to provide an accurate analysis, and

collection must be done twice or three times before being satisfactory. In borderline cases, results are not significant for CF, and further analysis is needed. Another problem is represented by the high levels of sodium and chloride in neonates who are otherwise normal. In these situations, we must wait and obtain another series of results after an interval of at least 1 month from the first test. More recently, the DNA probe analysis test for the ΔF-508 mutation and other common alleles allows for a precise diagnosis, which misses only a very small percentage of patients affected by CF. This method detects both affected children as well as heterozygote carriers.

Other causes of distal intestinal obstruction of the newborn may present with similar clinical patterns, including jejunoileal atresia, Hirschsprung disease, meconium plug syndrome, and neonatal small left colon syndrome. In particular, a congenital megacolon is suspected when the bowel contents are liquid and air–fluid levels are constantly seen in the dilated bowel.

Other conditions may mimic surgical obstruction, such as delayed peristalsis associated with prematurity (so-called functional immaturity) and adynamic ileus from sepsis. If a volvulus without malrotation or neonatal invagination is seen, the patient may undergo a sweat test to exclude CF. Although unusual, meconium ileus exists as an isolated entity, not associated with CF. These patients account for 6%–12% of the total, and the course of the illness is more often benign and without complications.[23]

MEDICAL AND SURGICAL TREATMENT

The first step of treatment includes a nasogastric tube decompression, an antibiotic prophylaxis with cephalosporin and aminoglycosides, and correction of dehydration, electrolytes, and hypothermia.

A contrast enema with water-soluble and hyperosmolar or iso-osmolar contrast is the medical treatment of choice without any mucosal damage, for uncomplicated meconium ileus. A recent study that used various enema solutions administered in a mouse model showed that surfactant and gastrografin were the most efficacious for the in vivo relief of constipation, in comparison with perflubron, Tween-80, GoLytely, DNase, *N*-acetylcysteine, and Viokase. Intestinal mucosal damage was absent, and viscosity was significantly reduced in vitro.[24]

Enema evacuation should be obtained under fluoroscopic control, with a gentle and progressive increase of the intraluminal pressure, thus avoiding unexpected fractures of the colon. A correct procedure prevents leakage of the contrast medium by taping the buttocks as well as catheter dislocation. If the contrast medium fails to progress into dilated small bowel loops, the presence of an acquired atresia is definite, and the radiologist must stop the examination because of a high risk of perforation. Fifty percent of neonates submitted for this procedure showed a benefit of enema alone over the next 48 hours, without any additional treatment: in some cases, a second enema may be used with a complete evacuation of the meconium filling the ileal loops. Acetylcysteine administered by mouth is useful and helps to relieve the obstruction. Radiographs are taken at 3-, 6-, 12-, 24-, and 48-hour intervals, with the aim of evaluating progression and possible complications. At this time feeding is begun. Hypovolemic shock and early perforation are around the corner, but an appropriate and meticulous procedure can avoid these complications.

When medical treatment is unsuccessful in spite of an uncomplicated meconium ileus, surgery is mandatory, and an open evacuation, resection, and ileostomy are the different options. In a simple meconium ileus, the surgeon should perform a minimal procedure to obtain a lumen free from all kinds of rubbish, such as pellets, sticky meconium, and sometimes, small calcifications. In this case, a limited enterotomy and repeated warm saline irrigations through a smooth catheter provide the best result. In this event, meconium discharge may be manually supported, using the enterotomy placed in the dilated hypertrophic ileum. The catheter is two-way directed with care, clearing the small as well as the large bowel. At the same time as the irrigation, the surgeon controls the enema progression, and the bowel may be inspected for degree of distension, mesenteric orientation, covered perforation, gangrenous tract, and atretic single or multiple segments. The colon is inspected too, searching for possible perforation or microperforation. T-tube ileostomy could be an additional effective and safe treatment, without any additional surgery in 90% of treated patients; the T-tube should be removed within the first 8 weeks after surgery.[25,26]

At the end of this treatment, discussion is about whether to resect or not, because some authors stress the risk of a leakage at the anastomotic site: we must keep in mind that resection and termino-terminal anastomosis is possible, only if any sign of infection or sepsis is absent. Usually, a resection is done with the aim to promptly restore normal peristalsis: in these patients, the intestinal resection is limited to a huge dilation, at risk for foci of regional infection. Actually, bowel resection with primary anastomosis has been proved to be as effective and safe as stoma formation and is associated with a reduced length of initial hospital stay.[20] However, in complicated forms of meconium ileus, primary resection and anastomosis should have some advantages, such as shorter hospital stay and no later surgical procedure of stoma closure.[27,28]

An ileostomy can be performed in different ways: the simplest one is a double-barreled ileostomy (Mikulicz), with the two loops brought out side to side; this solution is quick and avoids an intra-abdominal anastomosis. However, neonates may lose a large amount of fluids and solute from this through the ileostomy, and in selected cases, as an alternative to a peripheral line, a central venous catheter is scheduled, for both nutritional and medical purposes. More and more alternatives have been described: distal ileostomy with end-to-side ileal anastomosis (Bishop–Koop) has been called "distal chimney enterostomy." The proximal chimney enterostomy is the Santulli procedure, with a proximal

ileostomy with end-to-side ileal anastomosis. Complex meconium ileus or management with stomas significantly increases both length of stay and relaparotomy rate irrespective of the type of management.[29]

The enterostomy is closed between 7 and 12 days after surgery by an end-to-end anastomosis.

In a few selected cases, gastrostomy may be needed, but only when recovery of intestinal functions is expected to be delayed.

Generally, the shorter the duration of the intervention, the less extended the resection, the earlier the recovery of the peristalsis, and the less complicated and more uneventful the postoperative care.

Complications include pulmonary infections, which is the most important one, with an incidence of at least 8%–10%. Anastomotic leakage occurs for different reasons: a technical mistake, an insufficient blood supply, a distal unrecognized obstruction. Delayed recovery of peristalsis is another frequently observed complication and is due to an abnormal stretching of the intestinal walls during fetal life. Total parenteral nutrition is the support of choice, and a central venous catheter is mandatory in these situations.

PROGNOSIS

Meconium ileus may be an early indication of a more severe phenotype of CF. This is suggested by the significantly lower pulmonary function found in children with a history of meconium ileus compared to age- and sex-matched children who do not have meconium ileus.[30] The complicated form is susceptible to a higher number of long-term surgical complications, including especially small bowel obstructions and blind loop syndromes. Long-term complications in neonates affected by uncomplicated meconium ileus who were nonoperatively treated are never seen, and only mild and transient complications have been observed in newborns treated with minor surgical procedures, such as enterotomies and irrigations.

Survival of neonates with meconium ileus has improved over the last two decades because of neonatal intensive care, improved surgical technique, and medical treatment, but it has been shown that a delayed arrival at the hospital after the initial symptoms causes significant morbidity.[31] In general, an overall immediate survival of 90% is achieved using the modern protocols, and nearly all deaths are pertinent to adolescents. Only a few children die because of liver and or septic complications. Deaths are mainly due to staphylococcal or *Pseudomonas* sepsis, primary or secondary to pulmonary interstitial emphysema or to aspiration pneumonia. In a large series reported and analyzed by Fuchs,[8] only one child died because of meconium ileus itself. More recently, different studies suggest that adequate initial nutritional and medical management of meconium ileus further allows quite similar nutritional and lung wellness compared with children affected by early-discovered and symptomatic CF.[32] In conclusion, even if meconium ileus is often associated with longer hospitalization and surgical procedures, high-risk infections, and sepsis, an early diagnosis of CF does not impair the long-term pulmonary outcome in these patients.[33]

Meconium peritonitis

JOSE L. PEIRÓ AND JOSE BOIX-OCHOA

INTRODUCTION

Meconium peritonitis (MP) is an aseptic peritonitis caused by spills of meconium in the abdominal cavity through one or several intestinal perforations that have taken place during intrauterine life. Extravasation of sterile meconium into the fetal peritoneal cavity causes an intense chemical and foreign body reaction with characteristic calcification. Often, the perforation seals before the infant is born. Gastrointestinal perforations that occur following birth, even though the gut still contains meconium, should not be included in the syndrome of "meconium peritonitis," and constitute an entirely different group of clinical problems.[1]

MP was first reported by Morgagni in 1761 in *De Sedibus et Causis Morborum*. Simpson[2] managed to find 25 cases in 1838, and it was Agerty[3] in 1943 who reported the first successful operation.

The estimated incidence of MP is currently 1:30,000.[4]

A review of the world literature up to 2015 revealed 1934 cases of MP reported, with 1167 survivors (Table 61.1). Previous collected series have made this task easier.[5,6]

In the last 20 years, continuing progress in prenatal diagnostic procedures and postnatal intensive care has decreased mortality rates below 10% in some series,[7,8] and in our last experience, the mortality rate fell to 6.6%.

The current authors' experience is based on 67 cases of pure MP who underwent surgical treatment. All of these patients presented with the classical picture of MP at laparotomy and had histological evidence of (1) meconium inclusions (Figure 61.1) or reaction to foreign bodies, and (2) visible perforation or microscopic evidence of intestinal cicatrization.

ETIOLOGY

Intrauterine intestinal perforation may result from various causes. Patients with MP are divided into those with and without associated intestinal obstruction. In the case of MP without obstruction, there is no clear-cut explanation for the perforation. Various hypotheses, such as segmental absence of the muscular coats, absence of the muscularis mucosa,[9] vascular occlusion,[10] and general hypoxia of the fetus in the perinatal period,[11] have been put forward. None of these hypotheses has been substantiated. In the current authors' research with rats, it has been clearly demonstrated that all these findings are a consequence of MP and not primary etiology.[12] In our experience, intestinal atresia, intestinal volvulus, and meconium ileus constitute 94% of etiological factors (Table 61.2). Other causes include Hirschsprung's disease, meconium plug syndrome, congenital bands, internal hernias, Meckel's diverticulum, and rectal perforation. The incidence of cystic fibrosis in infants with MP was previously reported[13] to vary between 8% and 40%.

However, in some cases, it is impossible to find its etiology, in spite of pathological changes. The tabulation of the medical and perinatal reports demonstrated that 80% of these patients had neonatal anoxia and respiratory distress.

Labor research demonstrates the consequences of the hypoxia on the splanchnic area and blood distribution in the studied animals.[14]

If these findings are correlated with the current authors' studies, as happens in isolated focal intestinal perforations in extreme prematures, it can be postulated that there is diminished blood flow to the intestine of the hypoxic infant. The mucosa, which is very sensitive to ischemia, undergoes diminished mucin production and degenerative alterations. The proteolytic enzymes can now attack the bowel wall, which is normally protected by mucin. The consequence of this is a break in the mucosal integrity followed by perforation. Sometimes the "jamming" of this reflex mechanism prevents the return to normality and can cause such severe ischemia that it leads directly to a covered perforation. The less vascularized zones, and therefore the more exposed to ischemia and perforation, are situated in the ileocecal region and splenic flexure, where the current authors have found 60% of all idiopathic lesions.

Table 61.1 Mortality rate in MP among 1934 cases reported in the world literature

Years	Total	Survivors	Mortality (%)
Before 1952	100	8	92.0
1952–1962	102	19	81.4
1963–1968	145	51	64.8
1969–1988	752	375	50.1
1989–1995	210	150	28.6
1996–2004	374	343	8.3
2004–2015	253	221	9.0
–	1934	1167	39.6

Table 61.2 Associated congenital malformations and operative findings

Malformation	Total	Survivors	Mortality (%)
Intestinal atresia	38	34	10.5
Volvulus	12	7	41.6
Meconium ileus	11	7	36.3
Other	8	8	0

PATHOLOGY

In the current authors' experimental work[12] with rats, it has been shown that meconium gives rise to a peritoneal reaction with rapid fibroblastic proliferation enveloping the lesion. Later, foreign body granulomas and calcifications are seen. This reaction may be local or generalized, the parietal peritoneum having lost its sheen. The intestinal loops are intimately adherent structures with a fibrous tissue, which is difficult to dissect, calcifications or meconium inclusions are disseminated, and the perforation is hard to identify. When the intestinal perforation does not cicatrize and there is a fibrinous reaction instead, the consequence is the formation of a cyst, the walls of which are formed of fibrin, meconium, and intestinal loops intimately united. Such a cyst may occupy two-thirds of the abdomen (Figure 61.2). The possibility of meconium spreading out by a hematologic or lymphatic route (via the brain or lungs) has been described.[15]

Lorimer and Ellis[16] described three major types of MP: fibroadhesive, generalized, and cystic. Two other types that have been described are the healed form of MP and microscopic MP.

The fibroadhesive type is the result of an intense fibroblastic reaction in response to the severe chemical peritonitis caused by the digestive enzymes in the meconium. This type produces obstruction by adhesive bands, and the site of perforation is usually sealed off.

The cystic type occurs when the site of perforation is not effectively sealed, and a thick-walled cyst is formed by the fixed intestinal loops.[17] This condition prevents communication of the perforation with the remainder of the viscera. Calcium deposits line the cyst wall. The formation of a pseudocyst represents an attempted intra-abdominal healing process to confine the perforation.

The generalized type usually occurs perinatally.[18,19] Calcified meconium is scattered throughout the peritoneal cavity, and the bowel loops are adherent by thin fibrinous adhesions. In the current authors' experience, this is the most frequent type (74% of all cases).

The healed form of MP, presenting as an inguinal or scrotal mass, is clinically and pathologically of special interest. These patients usually present with no relevant recent clinical history, although the majority show a unilateral hydrocele at birth. Radiological studies of the scrotum and abdomen are usually helpful in making the diagnosis by demonstrating scrotal as well as peritoneal calcifications.[20–22] This combination is pathognomonic of MP.[20,23] In some cases, the peritoneal calcifications are the only symptomatology. In cases in which the diagnosis can be established clinically, no surgical intervention is necessary and, in the majority of these cases, the nodules regress spontaneously.[23,24] Microscopic examination of the resected specimen shows a fibrosis of the serous membrane, dissociation

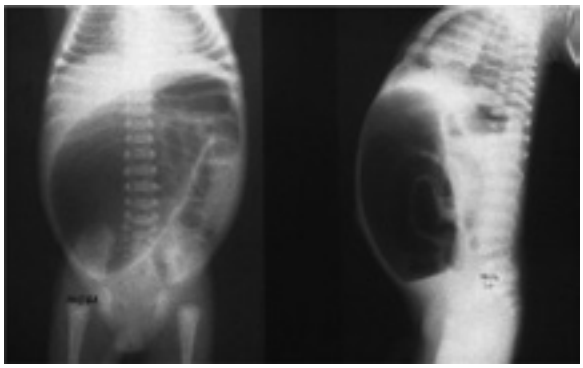

Figure 61.2 Typical roentgenogram of a giant meconium cyst. Prenatal ileal perforation was secondary to atresia of ileum.

Figure 61.3 Causal finding of calcifications on an intestinal atresia without the clinical evidence and operative findings of MP. This case is not included in our material.

of the muscular layer, foci of calcification, and granulomatous lesions with foreign body giant cells.

There is another type of microscopic MP described by Tibboel et al.,[25] without clinical or therapeutic significance. In the majority of cases, it is a casual finding during laparotomy for other causes (Figure 61.3). Many patients with this "microscopic" type of MP present with atresia, and the current authors feel that such an atresia should be regarded as scarring of the site of a perforation, which must have occurred at a relatively early stage of fetal development. A careful microscopic examination of the visceral and parietal peritoneum will, however, reveal bile pigment and/or squamous cell remnants. The presence of these meconium components proves that a perforation must have occurred. The presence of collagen, calcium deposits, and giant cells surrounding meconium particles indicates that the peritoneal cavity must have contained meconium for a considerable length of time. Its etiology should be examined for intestinal perforations at an early stage of development, resulting in intestinal atresia induced by a vascular lesion. At other times, the perforation can achieve complete recovery and not lead to any significant tissue deterioration; the only remnant of this pathology is the microscopic MP as a casual finding and without clinical significance.

Interleukin 6 and interleukin 8 play important roles in the inflammatory response syndrome associated with MP, and drainage of cystic fluid did not completely suppress this inflammation. These interleukin concentrations are elevated in patient's plasma, and very high in the cyst or ascites just after birth.[26]

SYMPTOMATOLOGY AND DIAGNOSIS

The diagnosis of MP in the postnatal period is based on clinical and radiological, and ultrasonographic findings of intestinal obstruction, and occasionally one or more of the following: calcification, pneumoperitoneum, cyst formation, or ascites. The clinical symptomatology is that of any intestinal obstruction. A typical baby with MP is born with abdominal distension, or develops it soon after birth, and this is accompanied by bile-stained vomiting and failure to pass meconium. Occasionally, severe abdominal distension may result in dystocia or respiratory distress. Sometimes, cryptorchidism is the indication that the fetal abdominal pathology has prevented the physiological descent of the testicles. Pathognomonic of this is the appearance of a scrotal edema or hydrocele with retention of the testes and intrascrotal calcification. X-ray and ultrasound[27] examinations show the intestinal ileus, the ascites when it exists, the ground-glass appearance of the abdomen due to the meconium, and rarely the presence of a pneumoperitoneum, since the quick formation of adhesions prevents the intestinal gas from escaping.

Intra-abdominal calcifications are characteristic[28,29] and can easily be seen on plain abdominal films (Figure 61.4). It is the current authors' belief that the origin of these calcifications may be the catalytic effect of the fatty meconial compounds on the precipitation of calcium salts. Proof of this is that in their investigations in laboratory animals with low serum levels of calcium, it has not been possible to reproduce calcifications. Faripor[30] is of the opinion that the pathogenesis of calcifications, after the analysis of seven cases with light microscopic observation, is undoubtedly in response to keratin debris. Keratin, however, cannot be the only source because of the presence of granulomas devoid of keratin. Due to the fact that some of these granulomas resemble gouty tophi, it may be as a result of inflammation caused by uric acid present in meconium. So early do the calcifications appear that the prenatal diagnosis of MP is easily made on sonographic exam,[31–37] finding fetal isolated intra-abdominal calcifications,[34] fetal ascites,[35] or meconium pseudocyst.[36] Diagnosis of associated pathology is

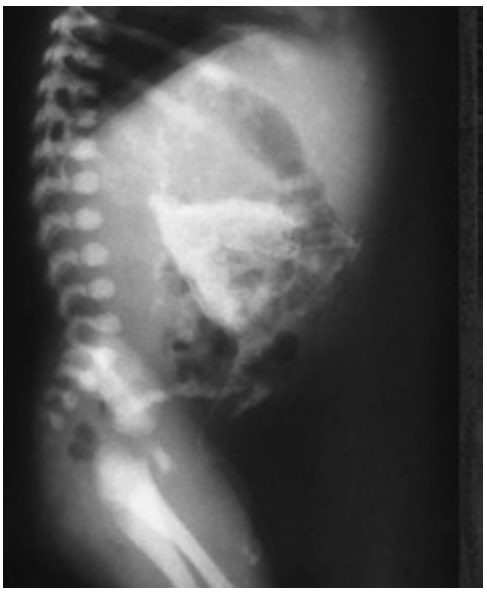

Figure 61.4 Pathognomonic abdominal calcification in a case of MP.

crucial because of its repercussions in the immediate postoperative period.[38] Finkel and Slovis indicate that the presence of intraperitoneal calcification does not exclude, but favors, a diagnosis of cystic fibrosis[39] in spite of the fact that they are scarcer than in the other types of MP. Detection of cystic fibrosis[40] is done by screening for the most common gene mutations and sweat chloride test, and also the recommended screening for congenital infections including herpes simplex virus, cytomegalovirus, parvovirus B19, and toxoplasmosis.

Newborns presenting with scrotal swelling with or without discoloration resulting from calcified meconium within the patent *processus vaginalis* have been described with increased frequency.[21,23] MP may result in a number of genital manifestations, including inguinal and scrotal or labial hydrocele containing meconium or calcifications and hard tumor-like scrotal masses.[41]

Early diagnosis is a decisive factor for the prognosis of these newborns, because bacterial colonization of the meconium starts after birth. In a study carried out by the current authors in 134 normal newborns, meconium cultures were positive in 24% at 12 hours of life and in 86% at 72 hours.[12] On the other hand, the laboratory studies carried out by the current authors already demonstrated the existence of a "meconium spreading factor," which accelerates and worsens the sepsis. Owing to this, it is not then surprising that early diagnosis is of paramount importance. In the current authors' series of 67 cases, the patients that were operated on after 36 hours of life had a mortality rate three times higher than those that were operated on during the first 24 hours of life (Table 61.3). Tibboel and Molenaar[6] reported a 91% mortality rate for patients operated on after 48 hours of life.

The natural history of MP diagnosed in utero is markedly different from that diagnosed in the newborn because some cases diagnosed prenatally normalize spontaneously during the gestational follow-up. The normal ultrasound features are polyhydramnios, fetal ascites, intra-abdominal calcifications, and dilated intestinal loops.[42]

Recently, it was reported[7] that magnetic resonance image afforded higher prenatal diagnostic accuracy of MP than ultrasonography (57.1% vs. 42%). Ultrasonography, however, is most widely used as a primary tool.

Zangheri et al.[8] proposed a prenatal classification that was divided into four grades of progressive severity, based on the number of pertinent ultrasonographic findings: grade 0, isolated intra-abdominal calcifications; grade 1, intra-abdominal calcifications and ascites, pseudocyst, or bowel dilatation; grade 2, two associated findings; and grade 3, all sonographic features. Patients with a score greater than 1 have a high probability for urgent neonatal surgery and therefore should be transferred in utero to a tertiary center with available neonatal surgery.

The cases in grade 0 that initial prenatal ultrasound findings subsequently disappeared during gestation can deliver at term without any complication at 40 weeks of gestation.

In fetuses with the described suspected intrauterine MP and pathological sonographic findings, an elective preterm delivery by cesarean section at a median gestational age of 35 weeks is recommended[43] in order to stop evolution of the disease and to operate the patient earlier. In the last years, with improvement in antenatal diagnosis, parents can decide termination of pregnancy in some cases of MP with other severe associated anomalies. Early detection is not associated with poor neonatal outcome, and selective termination is unnecessary.[44]

Dirkes et al.[13] reported that only 22% of fetuses with prenatal diagnosis of MP developed complications that required surgery, and the overall mortality rate in their series was 11%.

Meconium periorchitis is a rare disorder caused by fetal MP with subsequent spillage of meconium into the scrotal sac. The condition can be diagnosed during fetal life by ultrasonography, but usually diagnosed clinically during the first year of life, as an incidental finding of scrotal mass.[45] Surgical excision of the scrotal mass usually confirms the histological diagnosis of meconium periorchitis. Conservative treatment is also an alternative.[46]

Table 61.3 Time of operation related to prognosis

Time	Total	Survivors	Mortality (%)
<24 hours postnatally	25	23	8
24–36 hours	31	26	16.1
36–48 hours	6	4	33.3
>48 hours	5	1	80
	67	54	19.4

TREATMENT

After prenatal diagnosis or suspicion, currently there is not an established prenatal therapy. There is an isolated report that used fetal abdominal injection of urinary trypsin inhibitor to reduce the meconium-induced chemical peritonitis and avoid a postnatal surgery.[47]

After a prenatal diagnosis, sometimes, fetal paracentesis could be beneficial to reduce intra-abdominal pressure, to improve mesenteric vascular supply, and to remove inflammatory debris.[48,49] Antenatal diagnosis can help us to anticipate measures at delivery and be ready for an eventual need of immediate paracentesis and cardiopulmonary resuscitation.[50] The majority of fetuses with intra-abdominal calcifications on prenatal ultrasounds do not require surgery. Associated sonographic findings, as bowel dilation or suspicion of intestinal volvulus,[51] can be used to select fetuses for delivery in tertiary neonatal surgical centers.[52]

The indication for operation in newborns with MP is a clear sign of intestinal obstruction or perforation. The diagnosis of MP without intestinal obstruction or pneumoperitoneum does not constitute an indication for operation.

Infants with neonatal meconium calcification, meconium ascites with hydrocele, or calcified meconium found in the hernia sac do not require operation, but they have to be observed and feeding withheld for 48 hours. With absence of clinical symptoms, enteral feeding can be started with caution, gradually progressing to formula. Antibiotic coverage is desirable.

Surgical treatment

All the conditions for the preparation of the newborn for surgery, such as monitoring for vital signs and control of temperature with measures for impeding temperature loss in the operating theatre, should be adhered to. An intravenous cannula should be placed for intravenous fluid replacement. Blood should be cross-matched and prophylactic antibiotics started.

Operative treatment

Based on our experience of 67 cases with a survival rate of 92.8% in the past 20 years, the current authors act according to the following protocol:

1. If the perforation is visible, do not try to suture it. Intestinal resection and end-to-end anastomosis is performed.
2. In cases of localized or generalized peritonitis, attempt the lysis of the adhesions only to discover the perforation or to relieve obvious obstructions. Only when necessary should an attempt be made to dissect the adhesions, since fibroadhesive peritonitis disappears after 8–14 days; this has been confirmed in the current authors' patients who had the two-stage operation and investigation with laboratory animals.
3. Once the etiology has been determined (atresia, stenosis, or meconium ileus), an attempt must be made to perform an end-to-end anastomosis, according the Louw's technique,[53] if the general status of the patient and the discordance in the intestinal calibers allow it.

   Primary anastomosis can be performed for almost all patients with MP, except for nonstable extremely low birth weight infants.[54]

   The two-stage operation of Rehbein[9] (exteriorization followed by laparotomy and anastomosis) is used only if the patient's condition is very serious, or if the existing peritonitis can endanger the suture line, or when there are great differences in caliber of the two loops of bowel. The anastomosis is performed 2 weeks later, if the newborn's general status allows the second stage of the operation. During the interval between the two operations, enteral and total parenteral nutrition are indispensable for maintaining the newborn in the best condition as well as the stimulation of the distal portion with the contents of the proximal end. The two-stage operation offers a series of advantages that should always be considered by the surgeon:
   - Rapid resolution of the surgical problem.
   - It allows the surgeon to deal with the peritonitis, which would endanger the suture in a one-stage operation.
   - It allows recovery of the general state of the patient with the increase in energy reserves by means of parenteral nutrition and antibiotic therapy.
   - It gives time for the disappearance of bowel adhesions and the normalization in caliber and absorptive function of the intestinal mucosa by means of the growth stimulation offered by perfusion of the enteral diet through a soft silicone feeding tube in the distal portion.
   - It allows the maturation of the neuroendocrine system.

   The two-stage operation has been associated with a lower mortality rate in the current authors' series when compared with the one-stage operation (7.2% vs 22%).
4. When faced with a meconial cyst, in view of the small number of successful cases published,[16,54] the current authors always perform decortication with great care and a two-stage operation.[55]

   Another option is cyst drainage by ultrasound-guided needle punction and later laparotomy. A drainage procedure was always accompanied by supportive treatment of decompression, broad-spectrum antibiotics, and parenteral nutrition. Tanaka et al.[56] reported two cases of cystic MP that initially underwent emergency percutaneous drainage with ultrasonic guidance under local anesthesia. They found that such procedure is safe and effective in decompression of gastrointestinal tract and prevention of bacterial infection. They recommended cyst drainage just after birth and elective surgery later based on the general condition of the baby. During the second operation, the general condition is more stable and the adhesions will be less, the identification of the bowel loops easier, and the bleeding minimal.

To summarize, the current authors are convinced that the low morbidity rate can be achieved by the adequate planning of the operation in two stages, whenever faced with the slightest doubt as to the probable success of a primary anastomosis.

With antenatal and early diagnosis, the advances in surgical techniques, and postoperative treatment, current survival of the patients with MP is nearing 100%.[57]

COMPLICATIONS

Among the postoperative complications, adhesion obstructive ileus is the most frequent. In the current authors' series of 79 patients, 8 developed adhesion ileus, 5 had anastomotic leakage, 2 had necrosis of the ileostomy stump, and 1 had an enterocutaneous fistula. There were 14 deaths in the series, 7 directly attributable to lung complications in patients with cystic fibrosis; the other 7 patients died of sepsis. Also, there

are reported newborns that died from intraoperative hepatic hemorrhage, mostly in extremely low birth weight infants.[58] Gentle and delicate operative manipulation is required to reduce the mortality and morbidity in these cases.

Duplications of the alimentary tract

PREM PURI, ALAN E. MORTELL, AND FARHAN TAREEN

INTRODUCTION

Duplications of the alimentary tract are rare spherical or tubular structures that can occur anywhere in the tract from mouth to anus.[1–3] Calder reported the first case of enteric duplication in 1733, and Ladd,[4] in 1937, introduced the term *alimentary tract duplication* in the hope of clarifying the nomenclature, which had previously included descriptive terms such as *enteric or enterogenous cysts*; *giant diverticula*; *ileal, jejunal, or colonic duplex*; and *unusual Meckel diverticulum*. Ladd proposed that the unifying term *alimentary tract duplications* be applied to congenital anomalies that involved the mesenteric side of the associated alimentary tract; had a smooth muscle coat; shared a common blood supply with the native bowel; and were lined by gastrointestinal (GI)-type epithelium.[4] Most duplications might indeed be called simply *enterogenous cysts*, since in only very few cases is there an actual doubling of the alimentary tract, and these are therefore deserving of the name *duplication*.

EMBRYOLOGY

Numerous theories have been developed to account for the multitude of GI tract duplications. In a comprehensive review of GI duplications, Stern and Warner[1] outlined the most widely held theories regarding GI duplication.

Embryologically, duplications have been categorized into foregut, midgut, and hindgut types.[1] Foregut duplications include the pharynx, respiratory tract, esophagus, stomach, and the first portion and proximal half of the second portion of the duodenum. Midgut duplications include the distal half of the second part of the duodenum, the jejunum, the ileum, the cecum, the appendix, the ascending colon, and the proximal two-thirds of the transverse colon. The hindgut is composed of duplications of the distal third of the transverse colon, the descending and sigmoid colon, the rectum, the anus, and components of the urological system. In one series, 39% of duplications involved the foregut, whereas 61% represented duplications of both midgut and hindgut.[5]

Partial twinning

Certain duplications appear to represent partial twinning, particularly the tubular duplications of the terminal ileum and colon.[6–10] There is a wide spectrum of abnormalities, from complete twinning of the lower trunk and extremities to mere doubling of the lumen of hindgut structures. These lesions are often associated with duplication of the lower urinary tract.[11–13] Many rare examples of abortive cephalic twinning have also been described.[14] When there is complete doubling of the colon, one or both lumens may open as a fistula into the perineum or into the genitourinary (GU) tract and may be associated with an imperforate anus. Doubling of the anus, vagina, and bladder have all been detailed and often can be associated with other severe deformities, such as double spines or two heads.

Split notochord

The most satisfactory of several theories of the origin of GI duplications is that relating to the development of the neurenteric canal. Saunders,[15] in 1943, noted that thoracic duplications are frequently associated with abnormalities of the cervical and thoracic vertebrae. These duplications may be attached to the vertebral bodies or connected to the spinal canal. These findings gave rise to the Bentley and Smith *split-notochord theory*.[16–18] The embryo initially has two layers: ectoderm and endoderm. Mesoderm forms between the two, but for a short time, these two layers remain adherent. A transient opening (the notochordal plate) appears, connecting the neural ectoderm with the intestinal endoderm. This notochordal plate normally migrates dorsally and becomes "pinched" off from the endoderm by the ingrowth of mesodermal cells from each side. If the notochordal plate fails to migrate as a result of adhesions to the endodermal lining, the spinal canal cannot close ventrally, and a tract resembling a diverticulum is established with the primitive gut. This tract may remain open, leaving a fistula between the gut and the spinal canal, or close, leaving only a fibrous tract. However,

in the majority of cases, it disappears completely, leaving only the duplication of the GI tract. This theory explains the formation of thoracic and caudal duplications, which may be associated with vertebral anomalies. However, the absence of spinal defects in many alimentary tract duplications makes this theory less tenable as a unifying model of their origin.

Embryonic diverticula and recanalization defects

In a study on human (4–23 mm) and animal embryos, Lewis and Thyng[19] found tiny bands of intestinal epithelium protruding into the subepithelial connective tissue. The identification of numerous diverticula in the intestines of embryos led to the proposal of an extension of the diverticula into duplications. The frequent ileal position of these diverticula is congruous with the frequent ileal location of human GI duplications. Although this theory could explain duplications in the absence of spinal anomalies, it fails to account for the variability of the mucosal lining and specifically for the frequency of heterotopic gastric mucosa. Furthermore, the diverticula identified in this pathological series were located throughout the bowel circumference as opposed to the general locations of duplications on the mesenteric side of the intestine.

The occurrence of tubular duplications would also not be explained by this theory (Figure 62.1). Bremer[20] believed that abnormal recanalization of the intestinal lumen after the solid stage of development of the primitive gut in the sixth to seventh week of gestation resulted in duplications.[21] Such duplications, however, would not be confined to the mesenteric side of the bowel. Also opposing this theory is the finding that the solid stage of development in the human does not usually extend beyond the duodenum.[21]

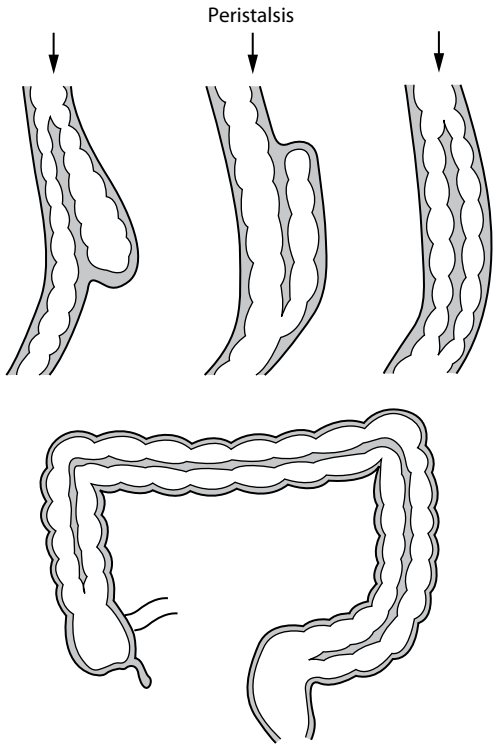

Figure 62.1 Various types of tubular duplications of the intestine.

In 1961, Mellish and Koop[22] proposed an environmental theory, which held that trauma or hypoxia could induce duplications and twinning in lower orders. Based on the work of Louw,[23] they concluded that vascular insufficiency could lead to the recognized GI duplications seen in humans. In addition, intrauterine vascular accidents are known precipitators of other congenital anomalies, such as GI atresias.

PATHOLOGY

Duplications are hollow structures that involve the mesenteric side of the associated GI tract.[24] They tend to share a common muscular wall and blood supply with its mature bowel, although each has its own separate lining.[25] They are usually isolated lesions and are more often cystic than tubular, with a variable size. The lesions have a muscular coat in two layers and are usually lined with epithelium similar to that found in the associated portion of the alimentary tract.[7] The duplications, however, are occasionally lined with heterotopic epithelium; the presence of colonic mucosa has been described at the base of the tongue, and sinuses lined with gastric mucosa have been found near the anus.[26] Duplications containing gastric mucosa are at risk of peptic ulceration, perforation, and hemorrhage.[27] Patches of ectopic gastric mucosa along the GI tract may represent the mildest manifestation of duplication abnormalities. Ectopic pancreatic tissue has been reported in duplications of the stomach, ileum, and colon.[28,29] The contents of a duplication vary with the type of epithelial lining of the structure, the presence or absence of a communication with the proximate part of the GI tract, and the absence or necrosis of the duplication wall. If an opening is present, the duplication contents will be similar to those of the adjacent intestinal tract. Communication between the two structures is rare, and the cysts usually contain chyle or mucus. Multiple duplications can occur in the same patient.[26,30] There is an increased incidence of other associated anomalies such as vertebral anomalies,[31] myelomeningocele,[32] imperforate anus,[33] malrotation of the bowel,[34] genital anomalies,[30] polysplenic syndrome,[35] and duodenal atresia.[36] No genetic tendency has been demonstrated.

Malignant carcinomatous changes are rare complications of intestinal duplications. Adenocarcinomas arising from small bowel as well as large bowel duplication cysts have been reported in adult life.[37–40]

INCIDENCE

Duplications of the alimentary tract are rare. Table 62.1 summarizes the larger published series of duplications. In many cases, the numbers of patients reported represent up to 40 years' work in these centers. Only a small percentage of the total cases reported actually presented in the neonatal period.[28,40–44]

Table 62.1 Incidence and locations of duplications

Author	Total no.	No. of neonates	Cervical	Mediastinal	Thoracoabdominal	Gastric	Duodenal	Jejunal–ileal	Colonic	Rectal

[a] One patient had two, one had three, and one had five duplications.
[b] One patient had three duplications.
[c] Two patients each had two duplications.
[d] Ninety-six patients had 106 atresias.

ESOPHAGEAL DUPLICATION

The esophagus is a relatively common site for foregut duplications (19%), with the majority being intramural, noncommunicating cystic structures related to the right side of the esophagus. Patients often present late in childhood as they cause relatively few symptoms; however, cervical esophageal duplications can cause significant respiratory distress requiring urgent surgery. Some lesions do not share a common wall with the esophagus and can be easily removed through open or minimally invasive techniques.[45] Plain x-rays may show an air- or fluid-filled structure adjacent to the esophagus, although this is not usually enough to confirm the diagnosis. Contrast studies can provide useful information regarding the mass effect of the lesion and whether or not their lumens communicate. Ultrasound and computed tomography (CT) are useful for establishing a diagnosis and also for ruling out multiple lesions, which can be present in 10%–20% of cases. Technetium scans (^{99m}Tc) may reveal the presence of heterotopic gastric mucosa in the case of GI bleeding.

Treatment

The surgical approach depends largely on the location of the cyst. Cervical esophageal duplications can be removed through a supraclavicular incision, with particular attention being paid to the vagus and phrenic nerves as well as the thoracic duct to avoid unnecessary damage. Intrathoracic duplications are resected through a standard posterolateral thoracotomy or a thoracoscopic approach.[46] A chest drain may be left *in situ* but is not always required.

THORACOABDOMINAL DUPLICATION

Thoracoabdominal duplications are rare, representing only 4% of all GI duplications. They often lie separate from the esophagus, more often on the right than the left side, but may be attached to other important structures, such as the aorta, azygous vein, and tracheobronchial tree. They frequently lie in the posterior mediastinum and pass through the diaphragm to communicate with the stomach, duodenum, or small bowel. The imaging studies employed are similar to those for esophageal duplications, with special attention being paid to imaging of the vertebral column/spinal cord for a possible intraspinal component. CT and/or magnetic resonance imaging (MRI) is particularly useful in this regard, especially if neurological symptoms of spinal cord compression or bony spinal abnormalities are present.

Treatment

These challenging duplications require resection of the thoracic and abdominal components through two different open procedures, or alternatively, they may be dealt with by a combined thoracolaparoscopic approach.[47] Although the abdominal portions are often asymptomatic, the thoracic components can cause symptoms as a result of mass effect on the lungs and airway. The presence of gastric mucosa within the thoracic duplication cyst can lead to peptic ulceration and possible erosion into the lung parenchyma, presenting with hemoptysis. This complication may require a lobectomy. Once the lesion is mobilized in the thorax, it is freed from the posterior aspect of the diaphragm prior to mobilization and removal of the abdominal component.

GASTRIC DUPLICATION

The stomach is one of the less common sites of duplications, accounting for only 9% of all GI duplications. Over 60% of cases are diagnosed during the first year of life, with a significant number (40%) appearing in the neonatal period through the finding of a palpable cystic mass in the upper abdomen accompanied by vomiting and weight loss.[48,49] Rarely, they undergo peptic ulceration, and if the cyst communicates with the stomach, hematemesis and/or melena may be the presenting feature.[27] Rarely, a carcinoma may arise within a gastric duplication cyst.[50] Gastric outlet obstruction, mimicking hypertrophic pyloric stenosis, is also a common presenting feature of this duplication.[51] Gastric duplications occur twice as often in females as in males.[24] Gastric triplication, although rare, has been described in the literature.[52]

It is often difficult to make a preoperative diagnosis of gastric duplication. Plain x-rays are usually negative and therefore unhelpful. A contrast meal may show compression of the stomach, usually along the greater curvature. Contrast may delineate a connection between the stomach and duplication, but only in a small minority of cases. In these cases, contrast may be retained in the duplication long after the remainder has passed from the GI tract. Ultrasonography has been shown to be useful in the diagnosis of gastric duplications. The vast majority of gastric duplications are located in the greater curvature (Table 62.2). Occasionally, these are pedunculated,[32,53] but most are closed spherical cysts or tubular structures.

Associated anomalies occur in 3% of gastric duplications.[54] The most common is another cyst, usually of the esophagus.[55] Dual duplications of the stomach and pancreas have been reported.[56,57] These are thought to arise from an error in rotation of the ventral pancreatic anlage.

Table 62.2 Location of duplications of stomach in 87 reported cases

Location	No. of cases
Greater curvature	55
Lesser curvature	7
Anterior wall	9
Posterior wall	9
Others	7

Treatment

The management of gastric duplications is surgical because of the high incidence of complications due to obstruction, bleeding, or peritonitis. As most duplications occur in the greater curvature, a wedge of stomach is excised together with the cyst and the gap closed with a single layer of horizontal inverting mattress sutures (Figure 62.2). Partial gastrectomy should be avoided in children if possible, and if necessary, only 25%–30% of the stomach should be resected because of the associated long-term complications. When extensive resection of the adjoining stomach is impractical, as with the long tubular duplications of the greater curvature (Figure 62.3a), the main part of the duplication is excised and the mucosa stripped off (Figure 62.3b). The remaining seromuscular cuff can be sutured over the denuded area (Figure 62.3c) after checking that the common wall between the stomach and duplication has not been perforated, by insufflating the stomach with air. The use of a stapling gun to divide the common wall along the length of the greater curvature has also been described.[58]

PYLORIC DUPLICATION

True pyloric duplications are extremely rare, with very few being reported in the English literature and most of these presenting within the first week of life.[48,59–62] They simulate the symptoms and signs of hypertrophic pyloric stenosis.[63] Vomiting, weight loss, and a palpable abdominal mass are the main findings. There are certain physical features that are consistent with duplication: the mass is usually large and smooth, in contrast to the smaller and often more mobile "olive" mass in hypertrophic pyloric stenosis.[63]

Because of the nonspecific physical examination, radiographic procedures are essential for diagnosis. Plain film x-rays may show signs of gastric outlet or duodenal obstruction with a lack of distal bowel gas,[64] or rarely, calcification within a cyst wall.[65] Ultrasonography may demonstrate an inner echogenic mucosal layer and outer hypoechoic muscular layer differentiating the duplication from a mesenteric cyst. Contrast studies may help differentiate the duplication from pyloric stenosis. If there is a clinical concern, then preoperative endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic cholangiography (PTC), or magnetic resonance cholangiography/pancreatography (MRCP) should be performed to evaluate the involvement of the biliary/pancreatic ducts.

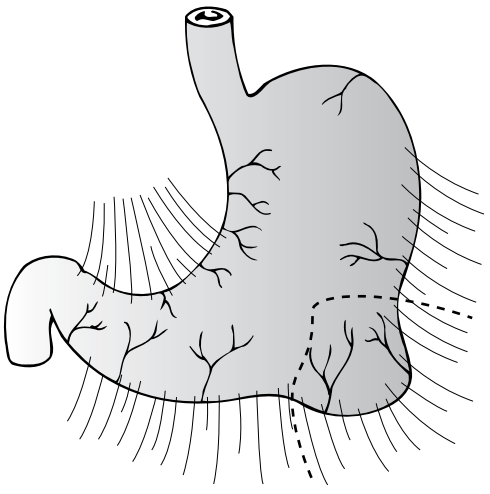

Figure 62.2 Gastric duplication located at the greater curvature. A wedge of stomach is excised together with the cyst and the gap closed with a single layer of horizontal inverted mattress sutures.

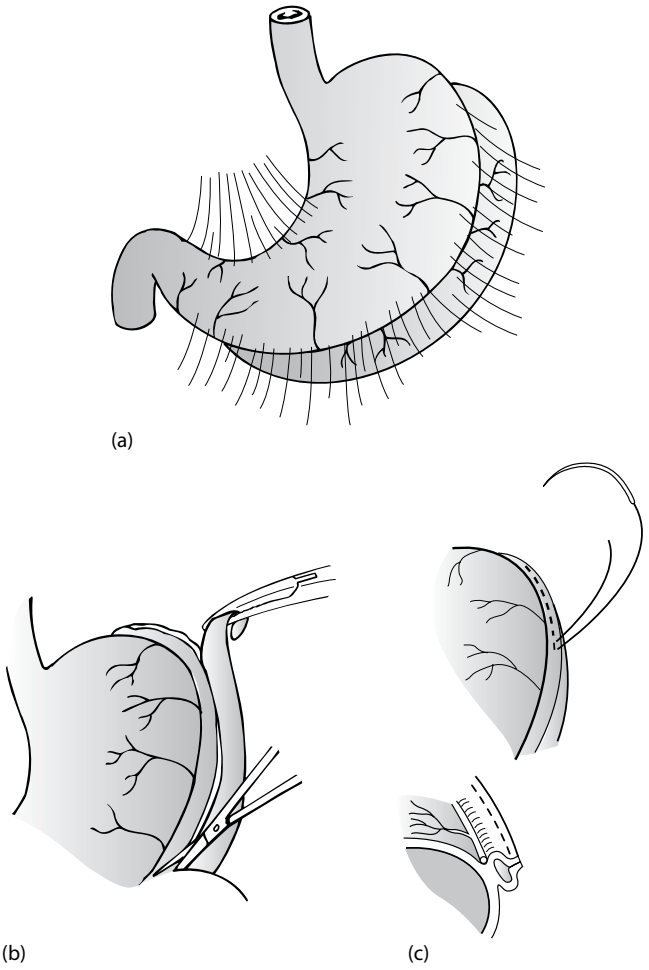

Figure 62.3 **(a)** Tubular duplication of the greater curvature of the stomach. **(b)** The mucosa is stripped from the entire length of the duplication. **(c)** The seromuscular cuff is closed over the denuded area.

Treatment

Of the cases of pyloric duplication reported, the majority underwent simple surgical excision after opening the pyloric canal longitudinally. The pylorus was then closed transversely with no complications.[48,58,61] However, if there is a risk of damage to pancreatic or bile ducts an, acceptable

alternative is to drain the cyst into the duodenum or into a Roux limb of upper small bowel.

DUODENAL DUPLICATION

The duodenum is involved in only 4% of all duplications. They are often behind the duodenum and do not communicate with the bowel lumen.[66] Vomiting secondary to partial or complete duodenal obstruction and an upper abdominal mass are present in the majority of cases.[67] They may present with hematemesis or perforation, as gastric mucosa is present in 10%–15% of cases.[68] Alternatively, because of their location, they may present with biliary obstruction or pancreatitis. If the duplication is of sufficient size, it may appear on plain x-rays as a large opacity in the right side of the abdomen displacing the intestine (Figure 62.4a). Contrast studies will show the duodenum to be displaced upward and a beak-like projection due to compression of the duodenal lumen by the duplication (Figure 62.4b).[69] Contrast entering into the cyst confirms the presence of a luminal communication. Ultrasonography may show a cystic lesion below the liver and a classical double-layered appearance or *muscular rim* sign (Figure 62.5a).

Treatment

In view of the occasional occurrence of gastric mucosa in the duplication cyst, these lesions should, if possible, be dissected from the duodenum and excised, closing the resulting defect in the duodenum in two layers. Intraoperative cholangiography will help determine the relationship of the cyst to the biliary and pancreatic ducts.[70]

If the lesion is extensive (Figure 62.5b), or if excision of the cyst may compromise the biliary system, then cystoduodenostomy may be performed.[71] The cyst may also be only partially excised, stripping off all the lining mucosa and leaving the part of the cyst that is adherent to the duodenum or pancreas.[70]

DUPLICATION OF THE SMALL BOWEL

Small bowel duplications constitute 45% of all alimentary tract duplications.[72] The vast majority of small bowel duplications are spherical cysts in the terminal ileum. Jejunal and ileal cysts are found on the mesenteric side of the bowel, sharing a common muscularis with the adjacent bowel. The mode of presentation depends on the site of the duplication, the mass effect of the lesion, and the presence of heterotopic gastric mucosa. They may cause obstruction by external pressure on the lumen,[73] by acting as a lead point for intussusception,[74,75] or occasionally by causing a volvulus or severe bleeding secondary to ulceration.[76]

Tubular duplications have the same features as the cystic variety, but they communicate with the normal lumen of the intestine and are more likely to contain gastric mucosa.[77] Pancreatic mucosa has also been described in these duplications. Tubular duplications can range in length from a few millimeters to the whole length of the small bowel.[78,79] The communication may be at the cephalad end, which will cause the duplication to become grossly distended with

intestinal contents, or at the caudal end, which will allow the duplication to drain freely. Communication at several different points may be present.

Hemorrhage occurs most often in tubular duplications, but perforation has been reported as well.[80,81] Plain abdominal x-rays may show nonspecific displacement of bowel gas shadows by the cyst, or signs of intestinal obstruction or perforation. Ultrasonography can help to differentiate between a mesenteric and a duplication cyst. A contrast meal may demonstrate displacement of the bowel (Figure 62.6).

Treatment

Cystic duplications are relatively straightforward to deal with. Resection of the cyst with adjacent bowel (Figure 62.7a) is performed; the two ends of the bowel are anastomosed

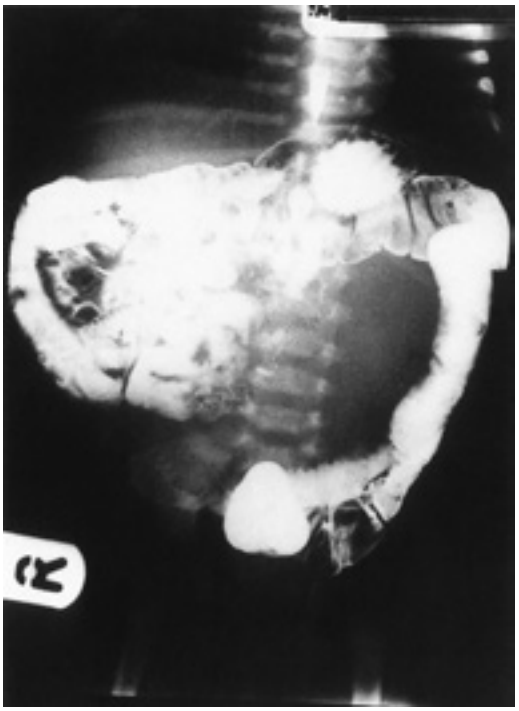

Figure 62.6 Barium study demonstrates a space-occupying lesion displacing bowel. At laparotomy, a large ileal duplication cyst was found.

with one layer of horizontal inverting mattress sutures, and the mesenteric defects are closed (Figure 62.7b).

Tubular duplications, if very short, can be resected as in a cystic lesion, but the majority involve a considerable length of small bowel, and much ingenuity and patience may be required to meet the needs of any one particular case.

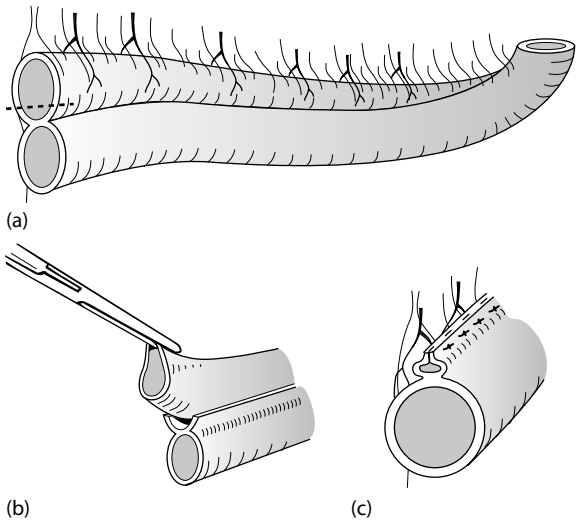

Figure 62.8 Tubular duplication of small bowel. **(a)** The main part of the tubular duplication is excised. **(b)** The mucosa is stripped from the entire length of the duplication. **(c)** The seromuscular cuff is closed over the denuded area.

Wrenn[82] suggested coring out the mucosal lining of a long tubular duplication through multiple seromuscular incisions in the wall of the duplication.

Norris et al.[83] employed a technique first described by Bianchi[84] for bowel lengthening, to separate two leashes of blood vessels passing to each side of the small intestine (Figure 62.8). Using this method, the entire mucosa and almost the entire muscle wall can be excised. The remaining cuff of muscle wall can be oversewn, preserving the blood supply to the normal bowel.

Bishop and Koop[85] described the techniques of anastomosing the distal end of the duplication to adjacent normal intestine, allowing free drainage of the contents. Malignant change in the mucosa has, however, been described as a late complication of this procedure.[86] Whichever technique is utilized, it is essential that the junction of normal and duplicated bowel is resected since heterotopic gastric mucosa is frequently present in tubular intestinal duplications.

COLONIC DUPLICATION

Colonic duplications are among the rarest reported. They are frequently diagnosed in infancy, and some reports suggest a female predilection. McPherson et al.[87] proposed a simple classification of colonic duplications: type I mesenteric cysts, type II diverticula, and the more common type III tubular colonic duplication. A number of etiological factors may be involved in the development of the "double colon." The most valid theory suggests division of the hindgut into two parts at a stage during which the anlage possesses a multiorgan developmental potential.[87,88] The hindgut anlage normally forms the distal ileum, colon, rectum, bladder, and urethra. Division of the anlage at the same initial stage could therefore be responsible for duplication of the lower urinary tract as well.[87]

Simple cysts (type I) and diverticula (type II) occasionally result. They can be identified on plain x-rays or on contrast studies. A contrast enema may demonstrate a communication between the colon and duplications in types II and III. Associated GU and lumbosacral spinal abnormalities can also be demonstrated on the appropriate radiographic studies, particularly when dealing with type III duplications. Isotope scans are rarely of benefit with colonic duplications, as they contain only colonic mucosa.

Complete duplication of the colon is usually asymptomatic in the neonatal period unless duplication of the anus or an abnormal orifice, in addition to the normal orifice in the perineum, is present. One or both orifices at the distal end of the colon may end as rectovaginal or rectourethral fistulas.[88]

Treatment

Surgery for colonic duplication is rarely indicated in the neonatal period unless there are complications, e.g., obstruction or an associated imperforate anus. All cystic and most tubular colonic duplications can be dealt with by simple resection and anastomosis utilizing a single-layer extramucosal technique. With rare total colonic duplication, the principal aim of management is to end up with two colons draining through one anal orifice. If one part of the colon has already reached the perineum, then the other colon is divided and anatomosed to its partner. This can be achieved by using a linear stapling device. If neither colon reaches the perineum, then a formal pull-through procedure will be required. Neonatal management in any of these situations is confined to fashioning a defunctioning colostomy to drain both colons.

RECTAL DUPLICATION

Rectal duplications have now been reported in the literature, comprising only 5% of all GI duplications. More than 50% of these are examples of hindgut twinning.[89]

The embryogenesis of rectal duplication cysts is attributed to a pinching off of a diverticulum in the 20–30 mm embryo,[90] in contrast to the "caudal twinning" that occurs in the 10 mm embryo and is associated with complex hindgut anomalies.[91,92]

Rectal duplications often present in the neonatal period with a fistula or perineal mucosal swelling extending to the perianal area. Presentation of the cysts depends on the following: (1) size and their mass effect, (2) fistulas,[93] (3) infection, (4) ulceration if they contain gastric mucosa, and (5) malignancy.[94] The duplication cyst usually forms in the retrorectal space and contains colorless mucus, which can become infected. It frequently presents in 20%–45% of cases.[89,90] No cases of a fistula between the rectum and urinary tract have been described. Malignant degeneration has been reported in the rectal duplication from the fourth decade onward.[95,96]

Treatment

Treatment of the rectal duplication cyst is surgical excision or fenestration of the common wall. Depending on the anatomical variations, a transanal or transcoccygeal (Kraske) approach can be employed. For longer or more complicated cysts, a longer posterior sagittal incision will provide better exposure. As with other duplications, it is of prime importance to remove all mucosa in the duplication. The muscularis can be left *in situ*.

Associated anomalies such as presacral tumors (16%) and anorectal malformations (21%) are frequently described in the literature.[97] Management of these lesions may be difficult and often requires preoperative evaluation of both the GI and GU tracts. Continence of both systems is imperative, and therefore, treatment strategies must be individualized based on the findings of each patient.

It is clear that duplications of the GI tract represent a diverse and complex group of anomalies. Small duplications in readily accessible areas (i.e., the small intestine) may be excised with adjacent bowel. In other locations, where resection would endanger adjacent structures, simple anastomosis between the cyst and normal intestine can be performed, provided that there is no gastric mucosa in the cyst. If bleeding has been a persisting complaint, the presence of gastric mucosa can be assumed. If resection is contraindicated, the lining mucosa may be stripped from the cyst, leaving the muscle wall *in situ*.

Mesenteric and omental cysts

BENNO URE AND CHRISTOPH ZOELLER

INTRODUCTION

The first report on a mesenteric cyst was published by an Italian anatomist in 1507.[1] Since then, the origin and classification of mesenteric and omental cysts have been a matter of debate. Moynihan[2] attempted in 1897 a differentiation of abdominal cysts on the basis of fluid content. Serous cysts are characterized by a translucent, straw-colored fluid of low specific gravity. Their chemical composition is similar to plasma. In contrast, chylous cysts contain an opaque fluid of high specific gravity, with lipids and fat globules contributing to the fluid content. Subsequent attempts at a more appropriate classification of intra-abdominal cysts have been based on suspected etiology initially proposed by Beahrs in 1950.[3] However, the etiology of many intra-abdominal cysts is questionable, rendering classifications of this type of limited clinical usefulness. A more appropriate classification, based on histologic findings, was proposed in 1987 by Ros et al.[4] This differentiation is applicable to all operative cases and can provide the basis for a more uniform evaluation of the clinical and pathologic characteristics of these cysts (Table 63.1).

Until today, the terminology is still descriptive of anatomic location without information as to the specific histology or pathology of mesenteric, mesothelial, or omental cysts. Several authors suggested differentiating cystic lymphangiomas from mesenteric and omental cysts.[5,6] A lymphangioma wall shows endothelial cells, small lymphatic spaces, lymphoid tissue, and smooth muscle cells. Mesenteric cysts do not have lymphatic spaces and smooth muscles, and the cells of their walls are cuboidal or columnar (Table 63.2).[5] All these cystic lesions are generally of isolated pathology, with few reports of associated developmental anomalies.

The incidence of mesenteric and omental cysts is rare and has not been systematically determined in the general population. Large reviews have indicated a male predominance.[7]

SPECTRUM AND MORPHOLOGY

Lymphangiomas represent approximately 90% of the cysts encountered in the mesenterium and omentum of the neonate. They are characterized by multiple thin-walled cystic spaces with a distinct endothelial lining similar to that seen in the subcutaneous location. These lesions are presumed to be congenital, with an etiology secondary to proliferating lymphatic tissue without access to adequate drainage. Lymphangiomas appear most frequently in the mesentery of the small bowel and may be encountered in the mesocolon and omentum. Extension to the retroperitoneum has been frequently described.[7,8] Gross, solitary, multiloculated, fluid-containing cysts are encountered, which can reach an enormous size (Figure 63.1). The fluid may be serous or chylous, with chyle being characteristic of a small bowel location and the associated high lymphatic fat content. Hemorrhagic fluid is not uncommon.

Mesothelial cysts are less common but represent the majority of nonlymphangiomatous congenital cysts encountered in the omentum (Figure 63.2). They may also occur within the mesentery. Mesothelial cysts are generally unilocular, serous-containing, and lined by mesothelium. They are thought to arise from incomplete fusion of the mesothelial leaves of the omentum or mesentery.

Enteric duplication cysts are not included under the heading of mesenteric cysts but should be mentioned due to their frequent neonatal presentation, mesenteric location, and occasional similarity in appearance. Therefore, they should be included in the differential diagnosis of intra-abdominal cystic lesions in the neonate. These cysts may occur anywhere along the gastrointestinal tract as saccular or tubular unilocular lesions, usually within the mesentery adjacent to a normal intestine (Figure 63.3). Histologically, they are composed of all the layers seen in normal intestine, and they share a common blood supply with the adjacent intestine. Duplication cysts may contain mucus-producing cells.

CLINICAL CHARACTERISTICS

The cysts may be diagnosed in utero with the use of routine prenatal ultrasonography.[19] However, most series report mean ages of 3–5 years at presentation,[10–12] and the age at diagnosis has gradually decreased over the years. Omental and mesenteric cysts may be an incidental finding, but more than half of these children present with acute clinical problems.

The symptoms of mesenteric or omental cysts are related to mechanical forces due to cyst location and size. The majority of children present with abdominal complaints, such as pain, vomiting, and distension (Table 63.3). Several authors have suggested that the high incidence of symptoms in children versus adults may be related to the higher incidence of lymphangiomas in young individuals.[7,8] A palpable

Table 63.3 Clinical presentation[1–4,5,6,7,10–13,18] (281 children)

Pain	41%
Mass	35%
Obstruction	32%

Miscellaneous[a]	23%

[a] Failure to thrive, nausea, gastrointestinal bleeding, diarrhea, etc.

mass is the most common physical finding, but this may be apparent in only 60% of affected children due to the flaccidity and mobility of the cyst. The mass, if present, is generally smooth, tender, and mobile in character. Of the affected children, 50% or more will present with complications. Intestinal obstruction, either partial or complete, is frequent and usually due to compression of the adjacent intestine. Volvulus can occur around the cyst and result in infarction of the bowel with perforation, peritonitis, and shock.[13] Hemorrhage within the cyst secondary to expansion or erosion may lead to rapid enlargement and pain as well as anemia.[14,15] Torsion of the cyst itself, rupture, and urinary obstruction have been reported.[14,16]

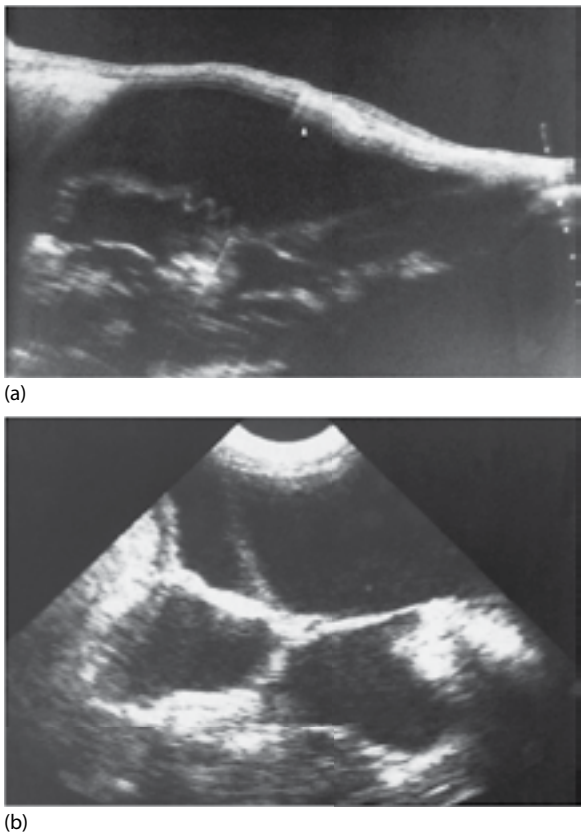
DIAGNOSIS

In most cases, a definitive preoperative diagnosis is not possible. Laboratory evaluation is pertinent only to complications that may be associated with the cyst. Sonography is the most useful diagnostic modality and represents the imaging technique of choice. The lesions appear as a well-defined, hypoechoic to anechoic smooth-walled mass, with echogenicity related to the cyst contents. In lymphangiomas, multiple thin septae may be apparent (Figure 63.4).

Computer tomography (CT) or magnetic resonance imaging (MRI) may be used in the differential diagnosis of these lesions. They frequently demonstrate a fluid-filled mass, but the thin septae, diagnostic of lymphangioma, may not be apparent. Ros et al.[4] suggested that a lymphangioma is usually a multiloculated cyst that shows no discernible wall on CT and that may have characteristics of fat. A basic radiograph of the abdomen is not routinely indicated and may demonstrate a mass, "ascites," or evidence of intestinal obstruction. Contrast radiography is rarely useful and may evidence a mass effect with varying degrees of compression of normal bowel in mesenteric cysts.

DIFFERENTIAL DIAGNOSIS

Other intra-abdominal lesions sometimes difficult to distinguish from a mesenteric or omental cyst mostly include ovarian cysts, choledochal cysts, pancreatic cysts, splenic cysts, renal cysts, hydronephrosis, cystic teratoma, dermoid cysts, hydatid cysts, and enteric duplication. The majority of these can be differentiated preoperatively by sonography and/or CT. Enteric duplication cysts have a thick wall and a common muscular wall with the adjacent bowel. A mucosal line may be visible on sonography.



(a)

(b)

Figure 63.4 **(a)** Longitudinal and **(b)** transverse abdominal ultrasound of a child with a large omental lymphangioma demonstrating a hypoechoic, septated mass immediately beneath the anterior abdominal wall.

Large cysts may mimic ascites in the neonate. Unless the ascites is loculated, shifting will occur with movement, and the bowel will flow centrally as opposed to in the lateral dislocation associated with mesenteric or omental cysts.

Remaining lesions commonly referred to as mesenteric and/or omental cysts are nonpancreatic pseudocysts with no distinct cellular lining. They are seldom encountered in the neonate and are secondary to inflammation or trauma. Because of this etiology, the contained fluid may be hemorrhagic or purulent. A nonpancreatic pseudocyst is usually a unilocular or multilocular cyst with abundant debris sonographically and an enhancing wall on CT. An enteric duplication cyst is a unilocular cyst but also with an enhancing wall.

TREATMENT

Preoperatively, the diagnosis may be in doubt, and parents have to be informed that management may require intestinal resection. Routine mechanical bowel preparation and intraoperative bladder catheterization are not required. Routine broad-spectrum antibiotics are only administered in cases with bacterial contamination, i.e., bowel resection.

In recent years, minimally invasive techniques have been suggested for the management of cystic abdominal masses and alimentary duplications.[17,18] The initial aim of laparoscopy is to locate the cyst and to determine its nature. The patient is placed in a supine position, and the surgeon, camera assistant, and monitor are placed in line. The optimal position of the ports is determined after exploration of the abdominal cavity via the first umbilical trocar. Mesenteric and omental cysts can be resected laparoscopically, but the location and fragility of the cyst wall may interfere with the feasibility of laparoscopy. Intraoperative aspiration of the cyst and subsequent analysis prior to removal are not indicated unless there is a question of biliary or pancreatic origin. Large cysts may be punctured to reduce the size and improve exposition, but this may make dissection more difficult. Management options include enucleation or resection. If any obvious plane exists between the cyst and the adjacent bowel wall, enucleation should be undertaken. In cases requiring a limited resection of bowel, the cyst and affected loop are exteriorized via the umbilical approach, and the resection and anastomosis are performed outside the abdominal cavity. Alternatively, a transverse mini-laparotomy may be used after the optimal location has been determined by laparoscopy.

The conventional operation is performed via a supraumbilical transverse approach. Omental cysts are generally immediately apparent upon entering the peritoneal cavity. They present as large, translucent, solitary fluid-filled sacs overlying the bowel. The omentum and associated cyst is gently withdrawn from the abdomen and placed on the abdominal wall. The cyst may then be easily removed by transection at the junction with normal omentum or transverse colon (Figure 63.5). Care should be taken to ligate the numerous omental vessels at the level of the transection. Larger mesenteric cysts may also be apparent upon opening the peritoneal cavity or, if they are smaller, require exploration. Once localized, the area of involvement is mobilized and eviscerated and the remaining bowel secured with sponges to facilitate exposure and resection (Figure 63.6).

If any obvious plane exists between the cyst and adjacent bowel wall, enucleation should be undertaken. In larger cysts, enucleation may require incision on both sides of the mesentery. Generally, a plane of loose areolar tissue is present, enabling mobilization. This may be facilitated with gentle downward traction on the cyst wall (Figure 63.7). Dissection is continued circumferentially until the cyst can be totally enucleated (Figure 63.8). Following enucleation,

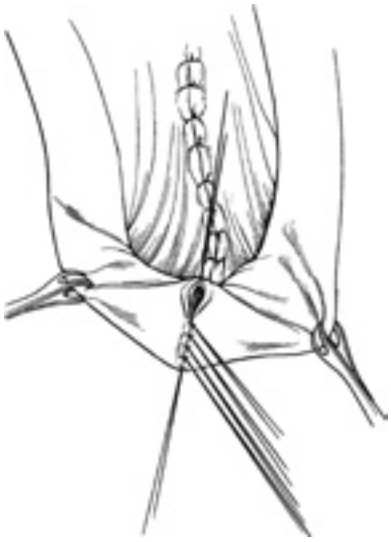

Figure 63.11 Reapproximation of the intestine with a single layer of interrupted absorbable sutures.

the mesenteric defect is closed, approximating both leaves of the mesentery (Figure 63.9).

In instances where a definite plane between the cyst and adjacent bowel cannot be identified, resection of the intestine in continuity with the cyst is required. Dissection should be planned so as to remove as little bowel as possible (Figures 63.10 and 63.11).

In patients in whom complete enucleation or resection cannot be achieved, partial excision with marsupialization and sclerotherapy are discussed. Application of agents like OK-432 remains highly controversial.[19–22]

OUTCOME

The outcome of resection or enucleation of mesenteric and omental cysts is very favorable. However, recurrence has been reported in up to 14% of patients, mostly with retroperitoneal cysts, which require re-resection.

Neonatal ascites

PREM PURI AND ELKE RUTTENSTOCK

INTRODUCTION

Ascites is defined as an abnormal accumulation of intraperitoneal fluid in the peritoneal cavity, which consists of transudate (low protein count and low specific gravity) or exudate (high protein count and high specific gravity). The relatively rare condition of ascites in the newborn may occur due to a wide range of medical and surgical causes. The surgical conditions that most likely result in neonatal ascites are obstructive uropathy, chylous ascites, and spontaneous perforation of the extrahepatic biliary tree.

URINARY ASCITES

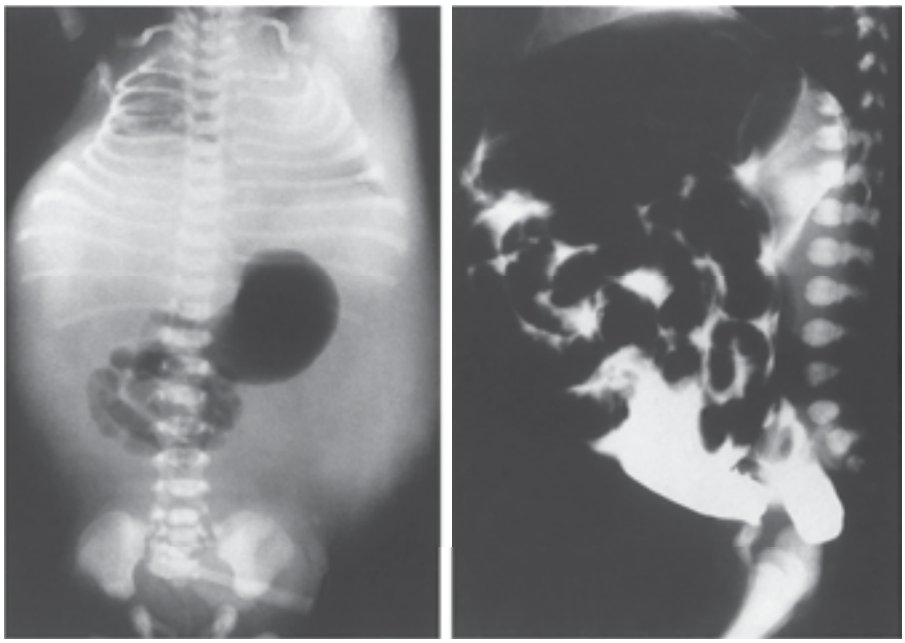
Urinary ascites, which occurs almost exclusively in boys, is an uncommon, life-threatening condition, which accounts for up to 30% of all cases of neonatal ascites.[1] Abdominal distension causing respiratory distress and signs of renal insufficiency are known as the most common presenting symptoms. Urinary tract obstruction from posterior urethral valves is the most common reported cause of urinary ascites, at up to 70%.[1,2] Other causes include ureteropelvic junction obstruction, ureterocele, lower ureteral atresia, bladder neck obstruction, and neuropathic bladder.[3] Ascites due to bladder rupture is also recognized, most commonly secondary to umbilical arterial catheterization causing rupture of the dome of the bladder or of a patent urachus. Predisposing factors apart from posterior urethral valves include neurogenic bladder, congenital bladder diverticulum, and detrusor areflexia. Spontaneous rupture of the bladder has also been reported as a result of profound hypoxia or morphine administration. Rarely, urinary ascites may occur in the absence of urinary tract obstruction.[4]

The ascites usually results from extravasation of urine into the peritoneal cavity due to urinary tract perforation above a point of obstruction. The perforation may occur in the bladder but most often occurs in the upper tracts.[3] In obstructive causes of extravasation, prolonged high pressure in the kidney leads to atrophy and dysplasia, which predispose to rupture of the collecting system. Urine may collect as a perinephric urinoma within the Gerota fascia encapsulating the kidney, or as urinary ascites in the peritoneal cavity.[5]

The presence of urine in the peritoneal cavity leads to an autodialysis effect, in which solutes and water follow their concentration gradients. This effect explains why ascites fluid shows sodium and potassium results not dissimilar from plasma, as well as hyponatremia and hyperkalemia. Furthermore, in all cases, one would expect higher levels of urea and creatinine with lower levels of bicarbonate in the ascites fluid than found in blood. This unique biochemical profile, in the presence of renal impairment, is peculiar to a diagnosis of urinary ascites.[6,7]

The diagnosis of urinary ascites is based on clinical assessment, together with ultrasonography and abdominal x-rays.[1,8] The typical patient with neonatal urinary ascites is a preterm male infant, who presents with gross abdominal distension, respiratory distress, and ascites at birth. Plain abdominal films will show diffuse opacity (Figure 64.1a). If the amount of intraperitoneal fluid is large, splaying of the lower rib cage and centrally located floating intestines will be demonstrated. Micturating cystourethrogram (MCUG) is necessary to diagnose posterior urethral valves, and ipsilateral vesicoureteral reflux may further elucidate the diagnosis (Figure 64.1b). Computed tomography (CT) has been recommended to reveal the underlying pathology.[9] Intravenous pyelography may show a characteristic "halo" sign produced by extravasation of contrast material into the perirenal area. Abdominal paracentesis confirms the diagnosis via elevated creatinine levels and urine in the fluid.[6,10]

The management of urinary ascites has to be prompt, with the basic aim of achieving decompression of the urinary tract. This may be accomplished by abdominal paracentesis, catheter drainage, or surgical exploration and repair of the bladder wall. One of the indications of abdominal paracentesis includes respiratory distress.[11,12] In cases of posterior urethral valves (PUV), catheter drainage by urethral route with or without vesicostomy achieves healing in most patients in 10–14 days. Catheter drainage fails in ruptures with large rents and requires surgical repair.[4]



(a) (b)

Figure 64.1 Urinary ascites. This infant had severe respiratory distress at birth due to gross abdominal distension requiring abdominal paracentesis. **(a)** Supine film immediately after removal of 650 mL of fluid shows stomach and small bowel loops floating centrally in the peritoneal fluid. Note splaying of ribs. **(b)** A micturating cystourethrogram shows leakage of contrast into the peritoneal cavity. Spontaneous perforation of the bladder was found at operation. There was no demonstrable anatomical obstruction in the urinary tract.

Long-term outcome of bladder and kidney function is reported to be surprisingly good in cases of neonatal urinary ascites secondary to severe obstructive uropathy.[3] Intrauterine pressure relief in the collecting system through urinary extravasation ("pop-off" mechanism) protects renal function, and this decompression of the urinary tract prevents severe secondary changes to bladder function.[13,14]

CHYLOUS ASCITES

Chylous ascites is a rare condition seen during the newborn period and infancy; however, it is a challenging disorder with regard to its successful treatment.[15,16] Generally, it presents with abdominal distension with or without respiratory distress and occasional signs of peritoneal irritation and malabsorption.[17] About 10% of all infants with chylous ascites have lymphedema of the limbs.[18] The most common cause of chylous ascites (45%–60% of cases) is congenital malformation of the lymphatic channels such as atresia or stenosis of the major lacteals, mesenteric cysts, and generalized lymphangiomatosis.[16,19] Other causes are obstruction of the lymphatics from external compression, as in malrotation; incarcerated hernia; intussusception; and inflammatory enlargement of lymph nodes. Furthermore, blunt abdominal trauma, child abuse, and surgical injury are reported causes of chylous ascites.[20]

Infants with chylous ascites present with abdominal distension at birth, or it may develop in the first few days of life. Ultrasonography of the abdomen is the initial step that confirms the presence of ascites. Abdominal paracentesis is not only a diagnostic but also a therapeutic method in the management of chylous ascites.[21] Analysis of the fluid obtained by abdominal paracentesis is the most useful diagnostic method. The chyle is usually color-free; however, its appearance and composition are not constant and depend on multiple factors such as the size of fat particles, cellular content, and diet.[22] After oral feeds have been started, the chylous fluid is milky white with a high fat content. Diagnosis is confirmed by determining high protein and triglyceride content in the ascitic fluid with predominance of lymphocytes on differential count. Initial diagnostic investigations include ultrasonography and CT or magnetic resonance imaging of the abdomen to exclude conditions that necessitate immediate surgical intervention. Diagnosis of malformation of the lymphatics is suspected when everything comes out negative. Further diagnostic tests like lymphangiography and lymphoscintigraphy are imperative if surgery is decided, with the purpose of identifying the site of the leakage of chyle preoperatively.[20]

Treatment of chylous ascites is usually conservative. The majority of patients respond to abdominal paracentesis and an enteral diet containing medium-chain triglycerides (MCTs) and high protein. Dietary management is an important treatment modality in chylous ascites. An MCT-based diet is accepted as the first measure to implement for reducing the chyle production in the peritoneal fluid.[23] MCTs are not re-esterified within the intestinal cell and thus bypass the enteric lymphatics and directly enter the portal system.

It is believed that the reduction in dietary long-chain fats (long-chain triglyceride [LCT]) reduces lymphatic flow and pressure within the lymphatic system and decreases the amount of lymph leakage. For severe or complicated chylous ascites or chylous ascites that persists after a maximum of 10 weeks of diet, total parenteral nutrition (TPN) has been successfully used in treating these infants by resting the gastrointestinal tract.[24] Somatostatin analogs have been demonstrated to be effective in reducing lymphorrhea and may be proposed prior to considering the surgical approach. The exact mechanisms of somatostatin on drying lymphatic flow are not completely understood. It has been previously shown to decrease the intestinal absorption of fats, lower triglyceride concentration in the thoracic duct, and attenuate lymph flow in the major lymphatic channels.[25] Satisfactory results were achieved by the administration of the somatostatin combined with TPN.[20,26] Surgical intervention is recommended if 1–2 months of conservative approach has failed.[27] Successful surgical treatment of congenital chylous ascites by resecting the macroscopically localized anomaly or by ligation of an identifiable lymphatic leak has been described.[28] A peritoneovenous shunt, of either Leveen or Denver type, also has been reported to be successful at least temporarily, in children in whom repeated attempts of a medical or surgical approach have failed.[16,29]

BILE ASCITES

Bile ascites in infancy is a rare condition usually resulting from spontaneous perforation of bile duct (SPBD).[30–32] Most often, SPBD is seen in infants aged 2–20 weeks, but it has been reported in neonates as young as 3 days.[31,33] The site of perforation is most often the junction of the cystic duct with the common bile duct (CBD). The exact cause of SPBD is unknown. Numerous etiologies have been proposed, such as congenital mural weakness of the CBD, ischemia, stones, infection, distal bile duct stenosis, inspissated bile, and pancreatic reflux from anomalous pancreaticobiliary ductal union (APBDU).[31,32,34] In the majority of cases, there is no apparent cause for the perforation. Some authors suggest that spontaneous bile duct perforation is not merely spontaneous, but may be related to APBDU and choledochal cyst; i.e., the perforation of the bile duct and congenital choledochal cyst may be interrelated problems with a common pathogenesis.[35] Occasionally, the perforation is secondary to bile duct obstruction.[36]

Affected patients are typically previously healthy infants with unremarkable birth and perinatal histories. Signs and symptoms generally appear gradually and subacutely, but they can also present acutely with peritonitis, septic shock, or even pulmonary collapse.[33,37] The classic subacute presentation occurs in 80% of infants with fluctuating mild jaundice, normal to acholic stools, slowly progressive ascites, and abdominal distension.[38] Associated symptoms may include sepsis, lethargy, irritability, anorexia, failure to thrive, persistent emesis, fever, and dark urine.[39]

The diagnosis may not be made before surgery but should be suspected in the presence of abdominal distension, intermittent jaundice, and ascites. Abdominal x-rays will show ascites, and barium meal may demonstrate collection of fluid between the liver and stomach (Figure 64.2). If paracentesis is performed, the concentration of bilirubin in the ascetic fluid is higher than in the serum. However, paracentesis is not necessary to establish the diagnosis if a hepatobiliary

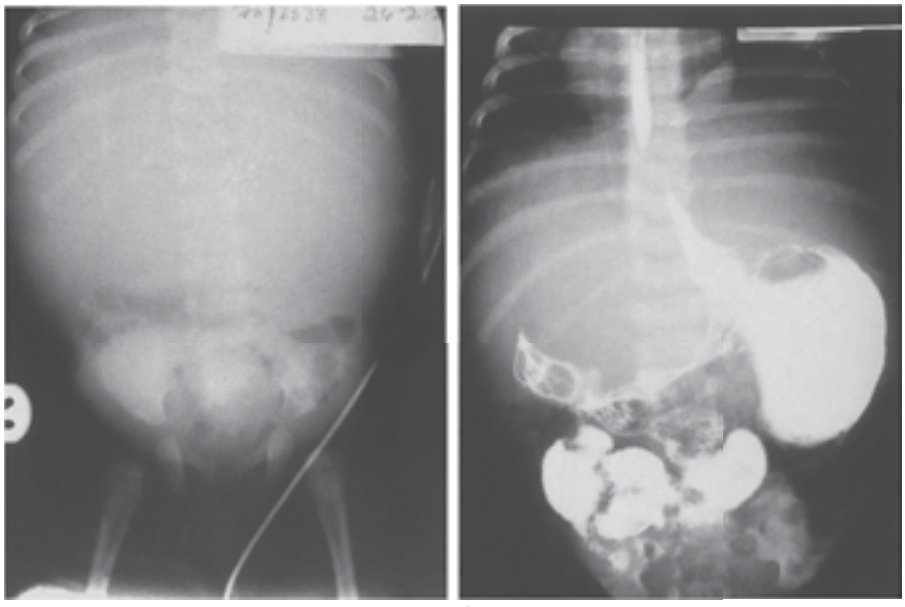


Figure 64.2 Biliary ascites. **(a)** Marked abdominal distention with opacity in upper and central abdomen and downward displacement of bowel loops. **(b)** Barium study shows compression with downward displacement of stomach and duodenum. At operation, perforation of the common hepatic duct was found.

scan confirms the presence of biliary leakage.[31] Ultrasound is the imaging modality of choice in children, especially for evaluating jaundice. Free or loculated intraperitoneal fluid with normal intrahepatic and extrahepatic ducts will confirm the presence of SPBD.[40] Hepatobiliary scintigraphy is highly sensitive and specific for SPBD, and it is the preoperative test of choice when SPBD is suspected.[39,41,42] It can provide useful information about liver function, biliary patency, site of perforation based on localized accumulation of radiotracer, and any biliary leakage into the peritoneum. Magnetic resonance cholangiopancreatography (MRCP) is also useful in children, including infants.[43,44] Loculated fluid collection or pseudocyst formation can be more easily visualized on MRCP than ultrasound.

Surgical management is mandatory as soon as the diagnosis of SPBD is confirmed.[45] An intraoperative cholangiogram should be performed to delineate the location of the perforation and exclude distal obstruction. If the perforation is in the gallbladder or cystic duct, simple cholecystectomy is curative.[31] Several surgical approaches have been described, including simple drainage with or without cholecystectomy, primary repair with or without external drainage, and hepaticojejunostomy if pancreaticobiliary malformation or distal obstruction is present.[41,46,47] Most authors recommend a conservative approach of draining the abdomen to decompress the biliary tree, unless there is distal biliary tract obstruction requiring biliary–intestinal anastomosis.[48] Spontaneous closure is typical even with distal obstruction, once the biliary tree is decompressed.[37] The drains should not be removed too early, since this can lead to reaccumulation of bile in the peritoneal cavity. In situations where the surgeon encounters biliary perforation without a preoperative diagnosis, the safest policy is to drain the area and place a T-tube through the perforation. Suture repair of the bile duct or biliary reconstruction remains controversial because of the potential for stricture formation.[49] Reported complications have included portal vein thrombosis, bile leak, and cholangitis.[50] In a few cases, further surgery, including biliary revision and portosystemic shunting, was reported.[50] Overall, the prognosis is good with early recognition and surgical management.

Necrotizing enterocolitis

STEPHANIE C. PAPILLON, SCOTT S. SHORT, AND HENRI R. FORD

INTRODUCTION

Epidemiology of necrotizing enterocolitis worldwide

Necrotizing enterocolitis (NEC) is predominantly a disease of the premature neonate. The majority of patients diagnosed with NEC are less than 32 weeks gestation. Data from population-based studies worldwide estimate the incidence of NEC to be 0.72 to 1.8 per 1000 live births.[1] The incidence is highest in extremely low birth weight infants (ELBW) weighing less than 1000 g, likely reflecting the degree of prematurity.[2–7] NEC decreases proportionally as birth weight increases, and a drastic decline occurs after 35 weeks gestation.[2,4,8]

The incidence of NEC has been increasing worldwide as a result of a steady rise in the rate of high-risk pregnancies and recent advances in neonatology that have resulted in the survival of significant numbers of ELBW infants.[9,10] Thus, the need to understand this disease has never been more imperative.

PATHOGENESIS

Risk factors

Early studies by Santulli and colleagues suggested that NEC develops in a susceptible or premature host as a result of various insults to the gastrointestinal tract inflicted by ischemia, enteral feeding, and pathogenic bacteria.[11,12] Our current understanding of the pathogenesis of NEC suggests that immaturity of the gastrointestinal tract in the preterm neonate, combined with these insults, accounts for the cascade of events that lead to NEC. The immature intestine is characterized by poor microcirculatory regulation, impaired integrity of the epithelial barrier, and various immune deficiencies, including decreased production of mucin, defensins, and secretory IgA, to name a few, which impair the host's ability to restrict the transmucosal passage of pathogenic bacteria and toxins. In addition, the dysfunctional motility and reduced digestive capacity of the premature intestine further predispose to the accumulation of toxins or noxious substances that may contribute to or exacerbate mucosal injury.[1,2] Although a normal intestinal microbiota could mitigate such mucosal injury, the premature neonate suffers from abnormal microbial colonization of the gastrointestinal tract. Thus, breakdown of the epithelial barrier is further exacerbated by loss of the vigorous and complex interaction between the mucosa and intestinal microbiota, which results in an inappropriate, exuberant inflammatory response to commensal and pathogenic bacteria. The inflammatory mediators released lead to further epithelial injury, exaggerated systemic inflammation, and the resulting adverse sequelae characteristic of NEC. The mechanisms that predispose the immature intestine to injury must be further defined in order to prevent or treat NEC in the premature neonate.[4]

Mechanisms of intestinal mucosal injury

Various studies describe some of the mechanisms by which mucosal injury occurs in NEC.[13,14] These studies have established a role for mediators such as nitric oxide, which is made in large quantities during inflammatory conditions by the inducible isoform of nitric oxide synthase (iNOS), and Toll-like receptor 4 (TLR4) in the pathogenesis of NEC. These mediators not only are elevated in neonates with NEC but also have been localized to regions of mucosal injury and have been shown to inhibit pathways necessary for restoration or repair of the damaged intestinal epithelium.[14–16] Inhibiting the activation of these mediators not only can reverse the inflammatory changes noted in the intestinal epithelium in experimental models of NEC but also can restore reparative pathways such as epithelial restitution through enterocyte migration and proliferation.[14] Interplay between these proinflammatory mediators and others such as platelet-activating factor (PAF) has been demonstrated and could represent putative pathways essential for the development of NEC.[17] Despite these observations, the sequence of events that lead to NEC has yet to be established. Nonetheless, targeted inhibition of these mediators

may ultimately lead to new therapeutic approaches to prevent or attenuate NEC.

Histopathologic findings

NEC can occur anywhere along the gastrointestinal tract but most commonly affects the small intestine.[18] Morphological analysis of resected, diseased intestine and autopsy specimens has historically shaped much of our understanding of the pathogenesis of tissue injury in NEC. On gross morphology, the bowel appears distended with patchy or diffuse areas of gray to dark discoloration. Focal lesions occur as commonly as multisegmental disease.[1,19] Examination of the mucosa may reveal a hemorrhagic and friable surface. Predominant histologic findings range from acute and chronic inflammatory changes to frank necrosis or perforation. These include bowel wall edema, submucosal gas, as well as neutrophilic and lymphocytic infiltrates, which may reflect in part the acuity or chronicity of the disease (Figures 65.1 and 65.2). Subserosal or submucosal gas, a product of bacterial fermentation also known as pneumatosis intestinalis, may also be visible and lends support to the infectious nature of NEC. Rapidly progressing injury to the bowel is suggested by necrosis in the absence of inflammation, also known as coagulation necrosis, while more gradual progression is suggested by the presence of chronic inflammatory changes.[20,21] Coagulation necrosis is often, although not exclusively, the result of ischemia. Coagulation necrosis may be limited to the mucosa; however, advanced disease may ultimately result in transmural involvement and perforation. Necrosis may be accompanied by hemorrhage and intramural thrombi. Reparative changes and granulation tissue have also been observed along with active injury. These findings suggest that the acute injury characteristic of NEC probably occurred prior to the clinical manifestations that required resection of the diseased intestine.[21] Patients with transmural inflammation that do not undergo resection may subsequently develop regions of submucosal fibrosis that can manifest clinically as intestinal strictures.

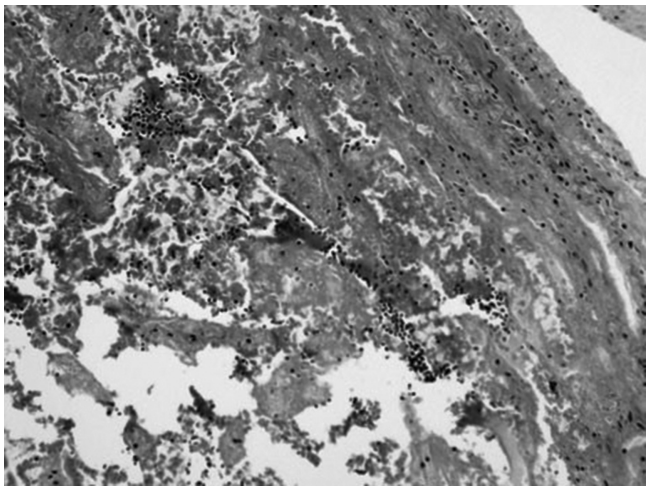

Figure 65.2 Dense lymphocytic infiltrate in the intestinal wall in NEC.

RISK FACTORS FOR NEC IN THE FULL-TERM INFANT

Fewer than 10% of patients who develop NEC are full term. While the pattern of mucosal injury reflects that of preterm infants, full-term infants differ clinically from their premature counterparts and, in this population, NEC "may be initiated by different perinatal factors."[22] Most studies suggest that congenital heart disease (CHD) is the most significant predisposing risk factor for NEC in the full-term infant.[22] Infants with CHD develop intestinal ischemia due to reduced blood flow to the intestine, which may result in mucosal injury and bacterial invasion, which in turn incites the inflammatory cascade that leads to NEC.

CLINICAL FEATURES

Presentation

At initial presentation, infants who develop NEC often exhibit nonspecific systemic signs that may prompt a workup for sepsis. Symptoms specific to the gastrointestinal tract are present in over 70% of patients and include feeding

Figure 65.3 Abdominal distention and extensive abdominal wall erythema in a patient with NEC totalis.

intolerance manifested by high gastric residuals or frank vomiting, abdominal distention, and gross or occult blood in the stool, which is seen in up to 60% of patients.[2] These symptoms may present postoperatively following the initial stages of cardiac repair for CHD in the full-term infant. As NEC progresses, patients may develop worsening abdominal distention, abdominal wall discoloration, or erythema (Figure 65.3). Within hours, patients can rapidly deteriorate and develop peritonitis with signs of cardiovascular collapse. The diagnosis is often established by radiographic imaging. Standard imaging consists of plain abdominal radiographs. Initial findings may be nonspecific such as dilated loops of intestine and a bowel gas pattern consistent with ileus. Pneumatosis intestinalis is the most common finding observed in patients with NEC (Figure 65.4).[1] Portal venous gas is another potential finding that is associated with pan-involvement and an unfavorable outcome (Figure 65.5). The NEC staging system, originally developed by Bell et al., combines the clinical symptoms with radiographic findings and has been used to classify severity of disease and guide therapy.

Laboratory findings

Laboratory data, although universally used, have not proven to be specific or reliable indicators for the diagnosis of NEC.

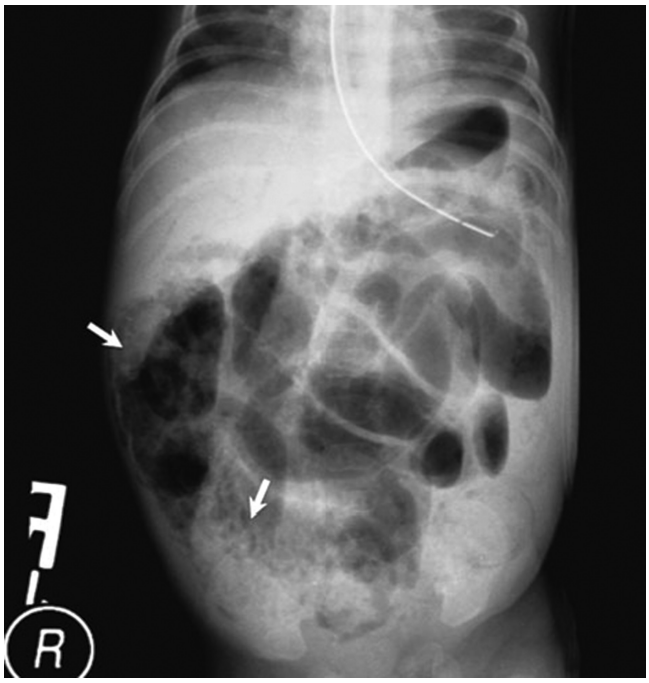

Figure 65.4 Pneumatosis intestinalis in a patient with NEC.

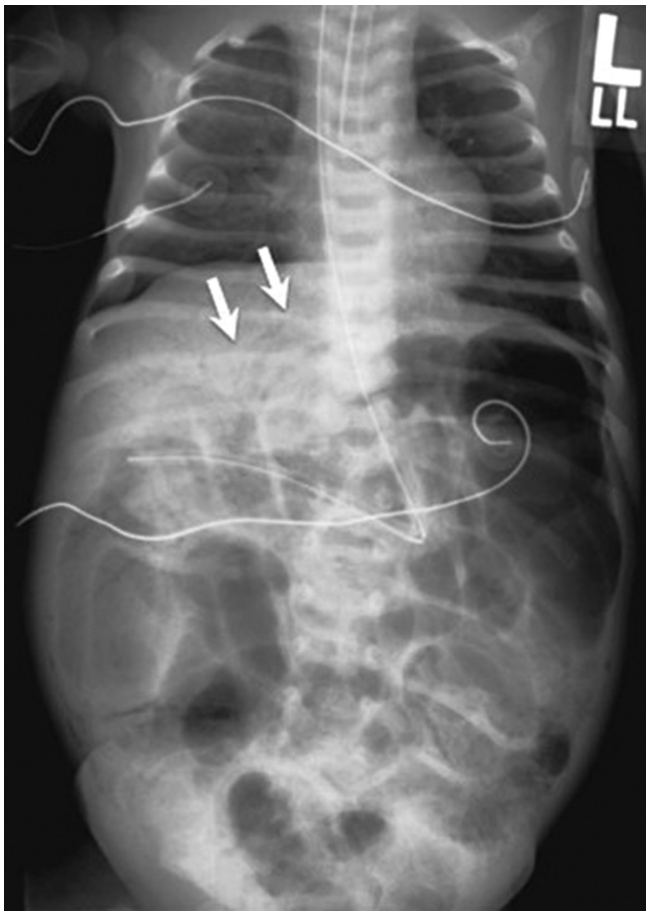

Figure 65.5 Portal venous gas in a patient with NEC.

Metabolic acidosis, leukopenia, and thrombocytopenia are common findings in patients with NEC.[1,2] Thrombocytopenia that occurs rapidly has been associated with a poor prognosis.[1,2] Studies have investigated potential indices predictive of NEC that may also serve as prognostic indicators; however, no inflammatory marker has emerged as highly sensitive and specific.[1]

ASSOCIATED COMORBIDITIES

Several retrospective studies have reported a high prevalence of NEC in patients who underwent abdominal wall closure for gastroschisis.[23–26] The patients described were often managed nonoperatively; however, recurrence was commonly observed.[23] NEC was significantly more common in patients with severe gastrointestinal dysfunction, characteristic of the premature gastrointestinal tract.

MANAGEMENT

Nonoperative

Patients with NEC are initially managed with supportive care. Upon clinical suspicion of NEC, feeds are withheld and the gastrointestinal tract is decompressed using an orogastric tube. Intravenous fluid resuscitation is initiated. Laboratory data including a chemistry panel, complete blood count with differential, blood gas, and C-reactive protein are obtained. Broad spectrum intravenous antibiotics are initiated once blood and urine are sent for culture. Close clinical observation with serial abdominal examinations as well as serial abdominal radiographs are used to monitor disease progression. Clinical improvement is expected to occur within the first 72 hours.[18] For patients who stabilize and show improvement, antibiotic therapy is continued for 1–2 weeks.

Operative indication and technique

Up to 20%–40% of patients with NEC will require surgical intervention.[1,2] Over the past decades, indications for operation have evolved as practitioners have sought to identify patients just prior to perforation; however, pneumoperitoneum remains the only consistent and definitive indication for surgical intervention. Relative indications for surgery include failure to respond to optimal medical therapy, as evidenced by worsening clinical status, abdominal wall erythema, or the presence of a persistent intestinal loop on serial abdominal radiographs. The goal of surgery is to resect gangrenous bowel while minimizing the risk of short bowel syndrome. The operation is largely determined by the extent of disease found at laparotomy. The entire length of the gastrointestinal tract is examined, and frankly necrotic bowel is resected. Where intestinal viability is questionable, a second-look laparotomy may be warranted. The standard surgical approach to the patient with NEC is resection of gangrenous or perforated bowel with creation of a proximal ostomy. Traditionally, enterostomy creation has been accepted as the safest approach because primary anastomosis may be tenuous in a septic infant.[27] For selected stable patients with localized disease, resection with primary anastomosis may obviate the need for a second operation as well as some of the morbidity associated with ostomy creation.[2,27] In the past, multiple stoma creation had been advocated for patients with multifocal disease. However, this approach can lead to short bowel syndrome by sacrificing viable intestine; therefore, it has been abandoned.

The "clip and drop back technique," which consists of resection of all necrotic bowel leaving the remaining clipped segments within the abdominal cavity without creating ostomies or anastomoses, has been advocated for patients with extensive multifocal disease. The viable segments are then re-anastomosed at a second operation 48–72 hours later. Delayed re-exploration has been proposed in a yet more controversial technique, the "patch, drain, and wait." This approach involves irrigation of the abdominal cavity, primary approximation of intestinal perforations, placement of a Stamm gastrostomy, and insertion of two Penrose drains beneath the diaphragm that course along the lateral aspect of the peritoneal cavity and exit from the lower quadrants for continued peritoneal drainage.[28] Postoperatively, patients are kept on long-term parenteral nutrition. The drains are left in place until the drainage ceases and patients are tolerating enteral feeds. The authors advocate postponing a second operation during the 2-week period immediately postoperatively, and in cases where return of bowel function does not occur, reoperation may occur as late as 2 months.

In the 1970s, peritoneal drainage was proposed as a temporizing measure for the critically ill very low birth weight (VLBW) patient, weighing less than 1500 g, with perforated NEC. The procedure is typically performed under local anesthesia at the bedside. The major components involve copious irrigation of the abdominal cavity and placement of a Penrose drain in the lower quadrant or bilateral lower quadrants allowing for decompression and removal of fecal contamination. Peritoneal drainage is widely viewed as initial treatment, and its use as definitive treatment remains controversial. There have been two randomized controlled trials investigating the use of peritoneal drainage versus laparotomy in VLBW infants with perforated NEC to determine any survival advantage. In the first multicenter trial, 117 VLBW infants were randomized to either treatment with 55 undergoing drainage and 62 undergoing laparotomy.[29] The investigators did not observe any significant differences in 90-day mortality. Similarly, no significant differences were observed in secondary outcome measures that included total parenteral nutrition (TPN) dependency and length of hospital stay at 90 days postoperatively. In the second international multicenter randomized controlled trial,[30] 35 patients were randomized to peritoneal drainage and 34 to laparotomy. There were no significant differences in mortality or in secondary outcome measures

that included length of stay and gastrointestinal and respiratory outcomes at 1 and 6 months postoperatively between the two groups. Seventy-four percent of the patients who underwent drainage subsequently required laparotomy for deteriorating clinical status. The authors concluded that peritoneal drainage is not "a safe alternative to laparotomy and is not an effective temporizing measure." While neither randomized trial detected differences in primary or secondary outcomes, each included a mixed population of patients with focal intestinal perforation and NEC, and the studies did not meet the minimum number of required participants for appropriate statistical power perhaps limiting the ability to observe differences.

OUTCOMES

Overall

NEC is associated with a high morbidity and mortality. Overall outcome is affected by the degree of prematurity and extent of disease. Over the past decades, survival for NEC has shown steady improvement. This observation has been most notable in VLBW infants and is likely related to advances in supportive care. NEC has a relatively low recurrence rate. Up to one third of patients with NEC will develop intestinal strictures. Strictures occur more frequently in patients with medically treated NEC.[2] Suspected patients should undergo contrast enema and surgical resection.

Postoperative outcomes

Postoperative complications occur in up to 40% of neonates who undergo surgical therapy for NEC. These include anastomotic leak, stoma complications such as prolapse or necrosis, and injury to the liver.[31] Other complications include intestinal strictures, sepsis, and short gut syndrome.[32,33] While mortality shows stepwise progression with decreasing gestational age, Horwitz et al.[32] found the overall number of complications to be relatively stable across all age groups.

Long-term outcomes

GASTROINTESTINAL

The most devastating complication of NEC is intestinal failure due to inadequate residual small bowel (short gut). Nearly one quarter of patients undergoing surgical resection for NEC will develop short bowel, and NEC is among the leading causes of intestinal failure in the neonatal population. Absence of the ileocecal valve does not always predict the likelihood of failure of intestinal adaptation in patients with inadequate small bowel length.[34] The patient's gestational age at the time of small bowel resection is an important prognostic indicator of the risk of intestinal failure because an increase in small bowel length typically occurs during the third trimester.[35]

Neurodevelopmental outcome

NEC has been found to be an independent risk factor for adverse neurodevelopmental outcomes. Analysis at 7 years for children included in the ORACLE Children Group, a randomized study investigating the use of broad spectrum antibiotics in preterm premature rupture of membranes, found increased risk of any functional impairment in children with a history of NEC.[36] In a multicenter retrospective study, ELBW infants who required surgery for NEC were found to have a significantly increased prevalence of neurodevelopmental and neuromotor or neurosensory deficits including cerebral palsy, blindness, and deafness.[37]

CONCLUSIONS AND FUTURE DIRECTIONS

NEC remains a vexing problem for both neonatologists and pediatric surgeons. The most devastating impact of this disease is its direct effect on patients and their families. NEC is also a major contributor to healthcare costs, and the economic burden persists beyond the initial hospitalization period. A retrospective cohort study found significantly higher healthcare costs for patients with both medical and surgical NEC compared with matched controls. These differences persisted through the first 3 years of life for patients with surgical NEC.[38] Thus, for the practitioner caring for these patients and their families, there is an urgent need to optimize current management and develop preventive strategies.

Although numerous studies have identified putative risk factors for NEC, preventive approaches are limited. Animal models have demonstrated a protective role for growth factors such as epidermal growth factor (EGF) and heparin-binding epidermal growth factor-like growth factor (HB-EGF), which can promote intestinal restitution, and for inhibitors of proinflammatory mediators. Studies in human infants have shown a beneficial role for probiotics and prebiotics in reducing the incidence of NEC and producing a fecal microbial composition that resembles that of their breastfed counterparts. However, there is insufficient evidence to recommend these interventions at this time. Restrictive feeding strategies have not shown any advantage. Corticosteroid administration has also been investigated as a therapeutic adjunct in NEC because of its ability to induce maturation of immature organs. The impact of corticosteroids on the developing intestine was first explored in the 1960s and was subsequently shown to accelerate the maturation of the mucosal barrier.[39] Randomized trials have demonstrated that steroids can reduce the number of patients who develop NEC as well as the severity of disease.[40,41] However, the direct impact of steroids on the gastrointestinal tract and their long-term effects on the developing intestine are not well defined. While antenatal steroids show benefit, use of postnatal steroids is cautioned since long-term outcomes will require further study.[42] Breast milk is the only intervention that is recommended for the preterm infant by the American Academy of Pediatrics to

prevent or reduce the incidence of NEC. Clinical trials have demonstrated the ability of breast milk to reduce the incidence of NEC and its associated mortality and morbidity among preterm infants, including improved neurodevelopmental outcomes. As studies on NEC continue, identifying the child at risk, advocating for the use of breast milk, and providing aggressive care will be key in managing this perplexing problem.

Spontaneous intestinal perforation

MARK D. STRINGER

INTRODUCTION

Spontaneous intestinal perforation (SIP) in the newborn, also known as focal, idiopathic, or isolated intestinal perforation, typically affects extremely low birth weight (ELBW; <1000 g) or very low birth weight (VLBW; <1500 g) premature babies. The perforation is most often located in the terminal ileum.[1] SIP can be difficult to distinguish from necrotizing enterocolitis (NEC), even though it is a separate clinical and pathological entity. If an infant with intestinal perforation is successfully treated by peritoneal drainage rather than primary laparotomy, the diagnosis of SIP is presumed rather than confirmed, and this has hindered interpretation of the literature. Reassuringly, however, in a large multicenter prospective study from the United States, 95% of babies undergoing laparotomy for presumed NEC or SIP were found to be correctly classified.[2]

EPIDEMIOLOGY

The incidence of SIP is approximately 1%–2% in VLBW infants[3,4] and 2%–5% in ELBW infants.[1,5,6] Boys are affected almost twice as often as girls.[4,7] The mean postconceptional age at birth of affected newborns is about 25–26 weeks, and mean birth weight about 720–820 g.[4,7] Prematurity is the single most important risk factor for SIP. Several related predisposing factors have been suggested:

Prenatal

- Chorioamnionitis—severe placental infection/inflammation and its associated treatment.[7–9] This may induce a vasculitic response in the fetus, which may in turn predispose the infant to SIP.
- Preeclampsia—identified as an independent risk factor in one retrospective study.[10]
- Maternal medication
  - Glucocorticoids. Although often stated as a risk factor, several studies have shown no association with antenatal glucocorticoids,[11,12] including one large retrospective study that included 280 babies with SIP.[13]
  - Nonsteroidal anti-inflammatory drugs have been proposed as a risk factor in one small uncontrolled study of SIP,[3] but the link remains unproven.
  - Magnesium sulfate (for fetal/neonatal neuroprotection).[14]

Postnatal

- Neonatal medication
  - Glucocorticoids. Dexamethasone given within the first week of life to prevent bronchopulmonary dysplasia in VLBW infants increases the risk of SIP,[4,12,15] but later administration of glucocorticoids does not carry this risk.[16]
  - Indomethacin. A link seems likely but the data are conflicting[4,12,13,17] and confounded by concurrent enteral feeding and glucocorticoid administration in ELBW infants. Indomethacin given for prevention of intraventricular hemorrhage does not appear to increase the risk of SIP,[18] while administration of indomethacin to treat patent ductus arteriosus does.[13]
- Hypotension requiring inotropes in the first week of life.[12]
- Delayed enteral feeding (beyond the first 3 days).[17]

PATHOLOGY AND PATHOGENESIS

The typical findings in SIP are those of a single perforation on the antimesenteric border of the terminal ileum, although perforation of the jejunum or colon has occasionally been described.[1,6,19–21] Rarely, a second perforation is

present.[6,22] The rest of the bowel appears normal, and peritoneal contamination is not usually severe. Histopathologic examination shows an area of discrete ulceration and hemorrhagic necrosis, unlike the ischemic and coagulative necrosis seen in NEC.[19]

The cause of SIP is unknown, but various pathogenetic mechanisms have been implicated:

- Thinning of the muscularis propria has been observed at the site of perforation[22,23] and variably attributed to either congenital deficiency of the muscle, localized increase in intraluminal pressure, or transient focal ischemia in utero.[22,24]
- Reduced activity of nitric oxide synthase (NOS) has been implicated in an animal model after ileal perforation was produced by the administration of indomethacin or dexamethasone to NOS knockout mice.[25] Depletion of NOS is associated with disturbed intestinal motility and reduced transforming growth factor-alpha in the muscularis propria.[26]
- Upregulation of genes involved in angiogenesis, cell adhesion and chemotaxis, extracellular matrix remodeling, inflammation, and muscle contraction are reported in intestinal biopsies from infants with SIP.[27,28] Elevated serum concentrations of interleukin-6, interleukin-8, soluble type II interleukin-1 receptor, angiopoietin-2, soluble urokinase-type plasminogen activator receptor, and tumor necrosis factor-alpha are also documented.[29] Gene upregulation is more marked and diverse and serum cytokine concentrations significantly greater in infants with NEC compared to those with SIP, adding further weight to the evidence that these conditions are both pathologically and clinically distinct.

There are some reports of an association between SIP and concomitant infection with coagulase negative *Staphylococcus* or *Candida* species,[1,8,30] but this is not a consistent finding and infection with these microorganisms is not uncommon in sick premature neonates.

CLINICAL FEATURES AND DIAGNOSIS

SIP occurs predominantly in VLBW or ELBW premature babies born between 25 and 27 weeks' gestation. The key differential diagnosis is NEC with gastrointestinal perforation. It is important to try and distinguish these two conditions because they are managed differently and have a different outcome (discussed next).

Table 66.1 summarizes the features of SIP that help to differentiate it from NEC. Babies with SIP have fewer systemic and abdominal signs preceding the perforation.[28,31] Median age at perforation is usually earlier than NEC, often within the first week of life but ranging from 0 to 15 days. In SIP, there is abrupt onset of marked abdominal distension, and the abdominal wall may develop a bluish discoloration. In NEC, the abdominal wall tends to become erythematous and indurated (Figure 66.1). The bluish discoloration has been highlighted by numerous authors,[1,6,19,30] but this feature is only a pointer to SIP and does not reliably distinguish it from NEC.[2,20,32] Unlike SIP, infants with NEC may have blood in the stools.[20] Both groups of infants may develop hypotension and metabolic acidosis.[4,20]

Laboratory features in SIP may include leukocytosis and thrombocytopenia and are not helpful in the differential diagnosis with NEC.[20]

Plain abdominal radiographs in SIP show a pneumoperitoneum but without signs of pneumatosis intestinalis or portal venous gas (Figure 66.2a). The pneumoperitoneum is usually obvious on a supine abdominal radiograph, e.g., the classical football sign or Rigler's sign. If there is only a small amount of free air, then a supine cross-table lateral shoot-through view may be helpful. The radiologic signs traditionally associated with NEC, namely, pneumatosis intestinalis and portal vein gas, are highly specific but relatively insensitive (Figure 66.2b). Only rarely is pneumatosis present in SIP.[20] Thus, the presence of pneumatosis intestinalis and portal vein gas is helpful in distinguishing NEC from SIP, but their absence is not.[33] In a minority of infants with SIP, the abdominal radiograph may initially be gasless[2,19] (Figure 66.3); in such cases, the presence of

Table 66.1 Differential diagnosis of SIP and NEC

	SIP	NEC
Median age at presentation (days)	7 (0–15)	25 (8–60)
Prodrome	Few systemic or abdominal signs preceding perforation	Often systemically unwell with abdominal signs before perforation
Clinical signs	Abdominal distension Bluish discoloration	Abdominal distension Abdominal wall erythema and induration
Radiologic signs	Pneumoperitoneum Gasless abdomen	Pneumatosis intestinalis Portal vein gas Fixed dilated small bowel loops Pneumoperitoneum
Laboratory features	Leukocytosis ± thrombocytopenia	

Figure 66.1 Abdominal wall discoloration in NEC. The abdominal wall is indurated and erythematous in contrast to the abdomen with SIP, which is distended and may have a bluish discoloration.

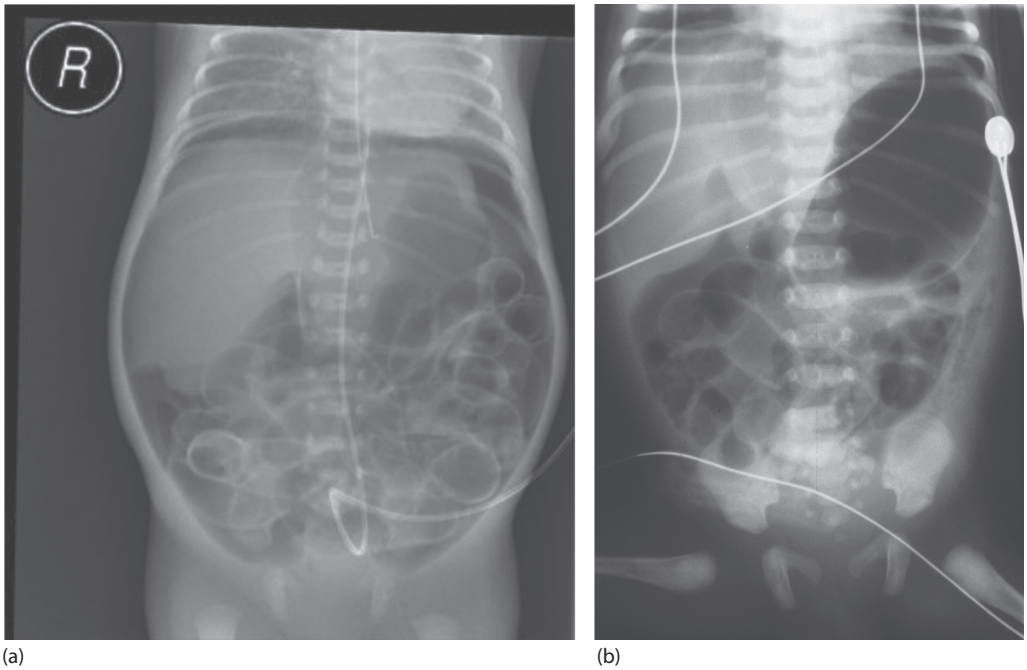
echogenic free fluid on an abdominal ultrasound scan supports the diagnosis of SIP.[32]

In summary, there are no clinical, laboratory, or radiologic features that can reliably distinguish SIP from NEC, but the earlier age of onset of the perforation and absence of pneumatosis intestinalis on the plain abdominal radiograph are features favoring the diagnosis of SIP.[2]

Other rarer differential diagnoses of SIP include (i) pneumoperitoneum secondary to pulmonary air leak, which may occur in infants who are ventilated or on continuous positive airway pressure (CPAP) and who have a pneumothorax or pneumomediastinum[34]; (ii) gastric perforation, which can affect a preterm newborn in the first week of life, although it is rare in ELBW infants[35,36] (see Chapter 54, this volume); and (iii) idiopathic pneumoperitoneum in a baby who is clinically stable and has no signs of peritoneal contamination.[37]

TREATMENT

Once SIP is suspected, enteral feeds and medications should be stopped and the stomach emptied by naso/orogastric tube. A double lumen gastric tube on low pressure suction is more effective at decompressing the gut than a standard naso/orogastric tube on free drainage and intermittent aspiration, especially if the baby is on CPAP. Other measures include intravenous fluids and broad spectrum antibiotics, analgesia, inotropes to treat hypotension that persists after fluid resuscitation, and parenteral nutrition. A prophylactic antifungal, e.g., fluconazole, is advisable.



(a) (b)

Figure 66.2 **(a)** Supine abdominal radiograph of a 7-day-old 24-week-gestation female infant with SIP. There is a pneumoperitoneum with a "football" sign (note the falciform ligament) and Rigler sign (air on both sides of the intestinal wall). Radiologic features of NEC are absent. **(b)** Plain abdominal radiograph of an infant with intestinal perforation from NEC. Note the free air, Rigler sign, and intestinal pneumatosis, which is maximal on the infant's left side.

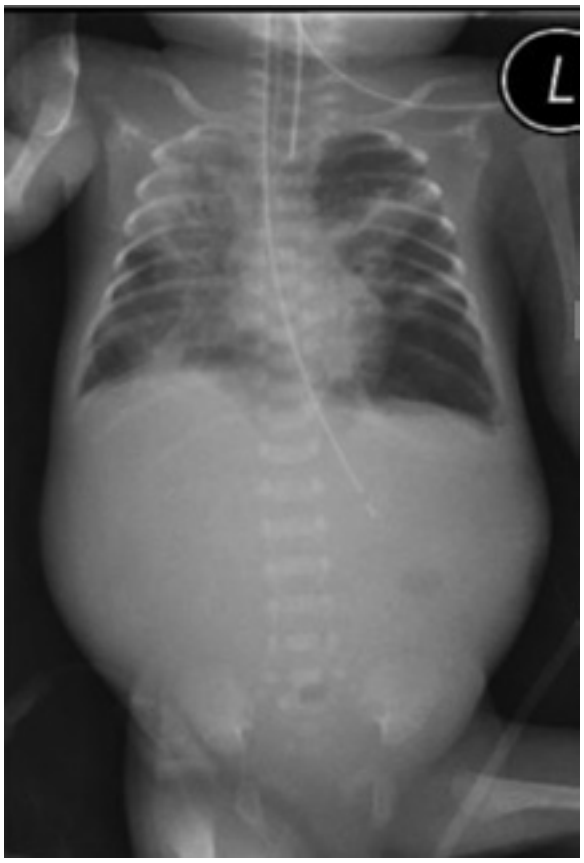


Figure 66.3 Almost completely gasless abdomen in a premature ELBW infant with chronic lung disease and SIP.

SIP is usually treated either by laparotomy and bowel resection[4,19,38] or by peritoneal drainage. Rarely, if the baby is stable, has minimal abdominal distension and no respiratory compromise, and the diagnosis of SIP is reasonably certain, the author has successfully managed the infant without any abdominal intervention. Primary peritoneal drainage (PPD) has the advantage of being performed at the cotside in the neonatal intensive care unit under local anesthesia. It avoids transfer of the baby to the operating room and the risks associated with general anesthesia and laparotomy. In many centers with modern neonatal intensive care, around 70%–80% of infants with presumed SIP treated by PPD will recover without the need for further surgical intervention[6,31,39–42] (Table 66.2). Unfortunately, there are no randomized controlled clinical trials (RCTs) comparing PPD and primary laparotomy in SIP. Such a study would be difficult to perform because in infants treated by PPD alone, the diagnosis of SIP is presumed rather than definite, and therefore some patients with SIP could, in fact, have NEC.

The reported outcomes for PPD in SIP underline the importance of attempting to distinguish SIP from intestinal perforation secondary to NEC because the utility of PPD in NEC is controversial (the evidence favoring primary laparotomy in most cases). Attempts to compare the efficacy of PPD versus primary laparotomy in premature low birth weight infants with intestinal perforation have been confounded by the inclusion of patients with either SIP or NEC. Despite this limitation, neither of the two published RCTs of PPD versus primary laparotomy in premature newborns with intestinal perforation showed a difference in mortality between the two treatment options.[43,44] However, 62% of VLBW newborns treated by PPD in the larger US study[43] avoided laparotomy (as compared to only 26% of ELBW infants in the international study[44]). Based on these two studies, a Cochrane review concluded that there was no significant benefit or harm from PPD versus laparotomy in premature VLBW newborns with intestinal perforation.[45] It should be emphasized that these studies did not differentiate patients with SIP from those with NEC. Recent retrospective reports indicate that PPD is likely to be significantly more successful in SIP than perforated NEC.[31,41]

Primary peritoneal drainage

The abdomen is prepped with antiseptic solution, and local anesthesia is injected around McBurney's point (two-thirds

Figure 66.4 Penrose drain in the right iliac fossa of a premature infant with SIP.

of the distance along a line from the umbilicus to the anterior superior iliac spine in the right lower quadrant). A small skin incision is made, and a hemostat is used to gently dissect through the layers of the abdominal wall, taking care to avoid visceral injury. On entering the peritoneal cavity, air and a small amount of bile/meconium stained fluid are released. A culture swab is taken, and a Penrose drain is gently threaded into the peritoneal cavity using the hemostat and secured with a single skin suture. The drain should be tunneled across under the anterior abdominal wall to the left side of the abdomen (Figure 66.4). Some reports describe exiting the drain in the left iliac fossa to facilitate irrigation of the peritoneal cavity with warm saline,[6,41] but such a maneuver may risk injuring the bladder[6] and is unnecessary.

Laparotomy

Laparotomy is necessary soon after PPD if the infant fails to improve, or there is a persistent leak of air or intestinal content or evidence of uncontrolled intra-abdominal sepsis.[39,42] Exploration usually reveals an isolated bowel perforation, most often in the ileum, and the presence of otherwise healthy bowel. The short affected segment of gut is resected followed either by primary anastomosis or the creation of proximal and distal stomas. In one small uncontrolled retrospective study of 23 infants who underwent primary laparotomy for SIP, mortality and morbidity were significantly greater after primary anastomosis than after stoma formation.[38] However, these results should be interpreted cautiously as 6 of the 14 infants treated by primary anastomosis developed postoperative NEC, which was fatal in 4.

If PPD is successful, wound drainage is minimal after 5–7 days, and the drain is then gradually removed by withdrawing it by about 1 cm each day. Antibiotics are given for 7–10 days. Once the drain is out and gut function has returned (as evidenced by a soft, nondistended abdomen in a baby who is stooling and has minimal clear gastric aspirates), enteral feeding is restarted. The author has not routinely performed a gastrointestinal contrast study prior to refeeding but reserves this investigation for those babies who fail to make the expected progress with enteral feeds.

If the newborn initially responds well to PPD, a laparotomy may yet be required subsequently for several reasons: persistent drainage of enteric fluid from the drain site indicative of an enterocutaneous fistula; recurrence of the pneumoperitoneum after the drain is removed (due to recurrent SIP or NEC); or intestinal obstruction, which may develop days or weeks after the drain has been removed due to intra-abdominal adhesions or a stricture at the site of the bowel perforation.[42] The drain site itself may be complicated by development of an incisional hernia.[39,41,42]

Later complications of SIP after PPD or primary laparotomy also include NEC.[21,38] Every effort should be made to reduce the risk of this complication by giving breast milk rather than formula feed.[46,47]

OUTCOME

The outcome after SIP has progressively improved such that 70% or more of affected newborns now survive in many units, whether treated by PPD or by primary laparotomy.[2,4] However, neurodevelopmental outcomes are worse than for unaffected infants of similar gestation and weight.[7,48,49] The overall prognosis tends to be worse for ELBW infants compared to heavier babies.[4,7] Mortality after SIP is reportedly lower than after surgically treated NEC,[2,4,12] but the morbidity in both groups is high because of their profound prematurity.

Hirschsprung's disease

PREM PURI AND CHRISTIAN TOMUSCHAT

INTRODUCTION

Hirschsprung's disease (HD) is a relatively common cause of intestinal obstruction in the newborn. It is characterized by absence of ganglionic cells in the distal bowel beginning at the internal sphincter and extending proximally for varying distances. The aganglionosis is confined to rectosigmoid in over 80% of patients. In the remaining patients, the aganglionosis extends beyond rectosigmoid involving descending colon and transverse colon, or it may involve the entire colon along with a short segment of terminal ileum. Total intestinal aganglionosis with absence of ganglion cells from the duodenum to the rectum is the rarest form of HD and is associated with high morbidity and mortality.[1–4]

The incidence of HD is estimated to be 1 in 5000 live births[5–8] (Table 67.1). Spouge and Baird[8] studied the incidence of HD in 689,118 consecutive live births in British Columbia and reported an incidence rate for this disease to be 1 in 4417 live births. Significant interracial differences in the incidence of HD have been reported: 1 in 10,000 births in Hispanic subjects, 1 in 6667 in white subjects, 1 in 4761 in black subjects, and 1 in 3571 in Asian subjects.[9] The disease is more common in boys, with a male-to-female ratio of 4:1.[5,10] The male preponderance is less evident in long-segment HD, where the male-to-female ratio is 1.5–2:1.[5–8]

ETIOLOGY

Neural crest cell migration

The enteric nervous system (ENS) is the largest and the most complex division of the peripheral nervous system. It provides the gastrointestinal tract with its unique network of innervation within its walls and functions largely independently of the central nervous system (CNS). The ENS contains more neurons than the spinal cord and is responsible for the coordination of normal bowel motility and secretory activities. Most of the neurons are located in either myenteric ganglia or submucosal ganglia and a few scattered within the mucosa. It is generally accepted that the enteric ganglion cells are derived primarily from the vagal neural crest cells.[11–14] During normal development, neuroblasts migrate from the vagal neural crest along the bowel wall in a craniocaudal direction from esophagus to anus. The embryonic neural crest arises in the neural tube, originating with the CNS, but neural crest cells detach from this tissue via reduction of cell–cell and cell–matrix adhesion. The epitheliomesenchymal transformation allows crest cells to migrate along pathways. Pathway selection is most likely achieved by balanced combinations of molecules that promote and reduce adhesion.

In the human fetus, neural crest-derived neuroblasts first appear in the developing esophagus at 5 weeks, and then migrate down to the anal canal in a craniocaudal direction during the 5th to 12th weeks of gestation. The neural crest cells first form the myenteric plexus just outside the circular muscle layer. The mesenchymally derived longitudinal muscle layer then forms, sandwiching the myenteric plexus after it has been formed in the 12th week of gestation. In addition, after the craniocaudal migration has ended, the submucous plexus is formed by the neuroblasts, which migrate from the myenteric plexus across the circular muscle layer and into the submucosa; this progresses in a craniocaudal direction during the 12th to 16th weeks of gestation.[15,16] The absence of ganglion cells in HD has been attributed to failure of migration of neural crest cells. The earlier the arrest of migration, the longer the aganglionic segment.

Several investigators have suggested that the enteric neurons follow a dual gradient of development from each end of the gut toward the middle, with vagal neural crest cells providing the main source of enteric neurons and sacral neural crest cells innervating the hindgut.[13,15,16] Whether the sacral neural crest contributes to the ENS in the human is less clear. Failure of the vagal derived neural crest cells to colonize the hindgut results in failure of ENS development in this region, suggesting that an interaction between sacral and vagal enteric neural crest cells may be necessary for sacral neural crest cell contribution to the ENS.[16]

Spouge and Baird[8]	1 in 4417	British Columbia	

Genetic factors

Genetic factors have been implicated in the etiology of HD. HD is known to occur in families. The reported incidence of familial cases varied from 3.6% to 7.8% in different series. A familial incidence of 15%–21% has been reported in total colonic aganglionosis (TCA) and 50% in the rare total intestinal aganglionosis.[17–19]

Recurrence risk to siblings is dependent upon the sex of the person affected and the extent of aganglionosis. Badner et al.[20,21] calculated the risk of HD transmission to relatives and found that the recurrence risk to siblings increases as the aganglionosis becomes more extensive (Table 67.2). The brothers of patients with rectosigmoid HD have a higher risk (4%) than sisters (1%). Much higher risks are observed in cases of long-segment HD. The brothers and sons of affected females have a 24% and 29% risk of being affected, respectively. The relationship with Down's syndrome also tends to suggest a probable genetic component in the etiology of HD. Down's syndrome is the most common chromosomal abnormality associated with aganglionosis and had been reported to occur in 4.5%–16% of all cases of HD.[22] Other chromosomal abnormalities that have been described in association with HD include interstitial deletion of distal 13q, partial deletion of 2p and reciprocal translocation, and trisomy 18 mosaic. Some of the syndromic forms of HD involve other cell types also derived from the neural crest, such as precursors of melanocytes for cranial pigment formation or in cells destined to function in the sensory components of the acoustic pathway. These include Sha–Waardenburg syndrome, Yemenite deaf–blind–hypopigmentation, piebaldism, Goldberg–Sprintzen syndrome, Smith–Lemli–Opitz syndrome, multiple endocrine neoplasia 2, and congenital central hypoventilation syndrome (Ondine's curse).[23–27]

During the past 15 years, several genes have been identified that control morphogenesis and differentiation of the ENS. These genes, when mutated or deleted, interfere with ENS development. So far, 22 genes are known to be involved in the development of HD (Table 67.3). One of these genes, the RET gene, encoding a tyrosine-kinase receptor, is the major gene causing HD.[19,28,29] Mutations in the coding region of RET are responsible for 50% of familial HD cases and 15% of sporadic ones.[19] All the genes that have been implicated in the development of HD together account for only 20% of all cases of HD.[19,27,30]

This implies that other genes are also involved in the development of HD.

Table 67.2 Recurrence risk to siblings

Relative	Recurrence risk (%)
Brothers of patients with rectosigmoid HD	?4
Sisters of patients with rectosigmoid HD	?1
Brothers of females with long-segment HD	24
Sons of females with long-segment HD	29

PATHOPHYSIOLOGY

The pathophysiology of HD is not fully understood. It has long been recognized that obstructive symptoms in HD are secondary to the abnormal motility of the distal narrow segment, but there is still no clear explanation for the occurrence of the spastic or tonically contracted segment of bowel.[31]

Normal intestinal motility requires coordinated interaction of ENS, smooth muscle cells, and interstitial cells. Several abnormalities have been described to explain the basis for motility dysfunction in the contracted bowel in HD.

Cholinergic hyperinnervation

In association with aganglionosis, there is a marked increase in cholinergic nerve fibers in the intermuscular zone and submucosa of the aganglionic segment. These fibers appear as thick nerve trunks and correspond to extrinsic preganglionic parasympathetic nerves.[32–36] The continuous acetylcholine release from the axons of these parasympathetic nerves results in an excessive accumulation of the enzyme acetylcholinesterase (AChE) that is typically found in the lamina propria mucosae, muscularis mucosae, and circular muscle with histochemical staining technique.[37] Both the thick nerve trunks and the increased AChE activity are most pronounced in the most distal aganglionic rectum and progressively diminish proximally as normal bowel is approached.[38] The proximal extent of increased cholinergic activity does not necessarily correspond to the extent of the aganglionosis, which usually extends more proximally to a variable degree. Pharmacologic investigations of the colon in HD have demonstrated higher acetylcholine release in the aganglionic segment at rest and after stimulation compared with the proximal ganglionic bowel.[39,40] AChE concentration has also been found to be higher in the serum and erythrocytes from children suffering from HD.[41] Cholinergic nerve hyperplasia has been proposed as the cause of spasticity of the aganglionic segment since acetylcholine is the main excitatory neurotransmitter.

Adrenergic innervation

Fluorescent–histochemical studies for localization of adrenergic nerves have demonstrated that they are increased in number in the aganglionic colon of HD and have a chaotic distribution. They are also present in the circular and longitudinal muscle layers as well

Table 67.3 Genes involved in the morphogenesis and differentiation of the ENS

Gene	Phenotype	Inheritance	Effects on intestinal innervation
RET	HSCR/HSCR-MEN2/FMTC	Dominant, incomplete penetrance	Absence of neuronal plexus in the small and large bowel TIA, renal agenesis
GDNF	HSCR	Dominant, low penetrance	Absence of neuronal plexus in the small and large bowel TIA, renal agenesis
EDNRB	WS4/HSCR	Recessive/dominant	Aganglionosis of the distal colon, coat spotting
SOX10	WS4/HSCR	Dominant	Aganglionosis, coat spotting
PHOX2B	CCHS/Neuroblastoma + HSCR	Dominant	TIA, no autonomic nervous system, ventilatory anomalies
NRTN	HSCR	Dominant, low penetrance	Moderate deficit of enteric neurons
PSPN	HSCR	Dominant, low penetrance	–
GFRA1	HSCR	Dominant, low penetrance	TIA, renal agenesis
EDN3	WS4/HSCR	Recessive/dominant	Aganglionosis, coat spotting
ECE1	HSCR with cardiac defects, craniofacial anomalies and autonomic dysfunction	Dominant	Aganglionosis, coat spotting, craniofacial defects
NTF3	HSCR	Dominant, low penetrance	Reduced enteric neurons
NTRK3	HSCR	Dominant, low penetrance	Reduced enteric neurons
PROKR1	HSCR	Dominant, low penetrance	–
PROKR2	HSCR	Dominant, low penetrance	Hypoplasia of the olfactory bulb and reproductive system
PROK1	HSCR	Dominant, low penetrance	–
SEMA3A	HSCR	Dominant, low penetrance	Deficit of cardiac sympathetic innervation and stellate ganglia malformation
SEMA3D	HSCR	Dominant, low penetrance	–
NRG1	HSCR	Dominant, low penetrance	Lethal from cardiac defect
NRG3	HSCR	Dominant, low penetrance	–
ZFHX1B	MWS	Dominant	Lethal at gastrulation
KIAA1279	GSS	Recessive	–
L1CAM	HSAS/MASA spectrum + HSCR	x-linked	Hydrocephalus

as in the mucosa, whereas they are almost not found in normal ganglionic colon.[42–44] However, the sensitivity of the aganglionic bowel to epinephrine is apparently not increased, despite the elevated number of adrenergic fibers.[45,46] The tissue concentration of norepinephrine is two to three times higher in the aganglionic bowel than in the normal colon; and also there is a corresponding increase in tyrosine hydroxylase, an enzyme that regulates norepinephrine biosynthesis.[43] Because adrenergic nerves normally act to relax the bowel, it is unlikely that adrenergic hyperactivity is responsible for increased tone in the aganglionic colon.[47]

Nitrergic innervation

Nitric oxide (NO) is considered to be one of the most important neurotransmitters involved in the relaxation of the smooth muscle of the gut.[48,49] It is synthesized in a reaction catalyzed by nitric oxide synthase (NOS) and depends on L-arginine and molecular oxygen as cosubstrates to form L-citrulline and NO. There are three archetypal mammalian NOS isoforms described: nNOS or neuronal NOS; iNOS, an inducible NOS isoform expressed in a variety of activated tissues; and eNOS or endothelial NOS.[50] NO binds to cytosolic guanylate cyclase and increases the production of 3′5′-cyclic guanosine monophosphate (cGMP) with subsequent relaxation of smooth muscle.[51] NOS has been shown to be colocalized with reduced nicotine adenine dinucleotide phosphate (NADPH) diaphorase, which has been demonstrated to have identical functions.[52,53] Several investigators have studied NOS distribution in the ganglionic and aganglionic bowel in patients with HD using NOS immunohistochemistry or NADPH diaphorase histochemistry.[54–59] In normal and ganglionic colon from patients with HD, there is a strong NADPH diaphorase staining of the submucous and myenteric plexuses, and a large number

of positive nerve fibers in the circular and longitudinal muscle as well as in the muscularis mucosae.[51] In the aganglionic segment of HD patients, there are no ganglia and there is an absence or marked reduction of NADPH diaphorase positive nerve fibers in both muscle layers and in the muscularis mucosae. The typical hypertrophied nerve trunks appear weakly stained.[51] Kusafuka and Puri[60] examined the expression of neural NOS mRNA in the aganglionic segment from seven patients who had HD and demonstrated that NOS mRNA expression was decreased at least 1/50 to 1/100 of the level expressed in ganglionic bowel. These findings indicate that there is impaired NO synthesis in the aganglionic bowel in HD, and this deficiency could prevent smooth muscle relaxation, thereby causing the lack of peristalsis in HD. In an interesting experiment, Bealer et al.[61] compared the effect of an exogenous source of NO, S-nitroso-N-acetylpenicillamine (SNAP), on the isometric tension of smooth muscle strips from aganglionic bowel and demonstrated a 70% reduction of resting tension. These results suggest that the defective distribution of nerves containing NOS may be involved in the pathogenesis of HD.

Interstitial cells of Cajal

Abnormalities of interstitial cells of Cajal (ICCs) have been described in several disorders of human intestinal motility including HD. Vanderwinden et al.,[62] using c-kit immunohistochemistry, first described that ICCs were scarce and its network appeared disrupted in aganglionic segments of HD, whereas the distribution of ICCs in the ganglionic bowel of HD was similar to that observed in controls. Yamataka et al.[63,64] found a few c-kit positive cells in the muscle layers in HD and a moderate number around the thick nerve bundles in the space between the two muscle layers in the aganglionic bowel. Barshack et al.[65] described abnormal ICC organization in the aganglionic and ganglionic bowel of patients with HD. Horisawa et al.[66] reported no differences in c-kit immunopositive cells in aganglionic segments compared with the corresponding area of ganglionic bowel. Rolle et al.,[51] using whole-mount and frozen sections stained with c-kit immunohistochemistry preparations, showed an altered distribution of ICCs in the entire resected bowel of HD patients and not only in the aganglionic segment. Moreover, gap junctions connecting ICCs were immunolocalized by anti-Connexin 43 antibody, found to be absent from the aganglionic part of HD bowel, and highly reduced from the transitional zone.[67] A scarce, disorganized, and impaired function of ICCs in the aganglionic and ganglionic bowel of patients with HD has been suggested to contribute to the persistent dysmotility problems after properly performed pull-through operation.

Platelet-derived growth factor receptor α^+-cells

Platelet-derived growth factor receptor α^+-cells (PDGFRα^+) have recently been documented in the human colon for the first time.[68] Previously known as fibroblast-like-cells, these cells are found to be distributed in a similar pattern as ICCs as well as morphologically resembling them. PDGFRα^+ cells are found alongside ICCs, neurons, and smooth muscle cells (SMCs) and appear to have a role in neurotransmission and the modulation of smooth muscle contraction.[69] We have recently discovered a decreased expression of PDGFRα^+ in HD colon, which suggests a role of these cells in the pathophysiology of this condition (see O'Donnell et al., article in press).

Enteroendocrine cells

Using the generic enteroendocrine cell immunohistochemical markers chromogranin A and synaptophysin, Soeda et al.[70] demonstrated that the number of enteroendocrine cells in the aganglionic colon in patients with HD was significantly increased compared with the number in the normal ganglionic segment. The increase in enteroendocrine cells in the mucosa of aganglionic colon may well influence sustained contraction of the bowel wall mainly mediated by the release of 5-hydroxytryptamine.

Smooth muscle

Smooth muscle cells are the effector cells of the bowel and, as a result of communication from the ENS, ICCs, and PDGFRα^+, govern intestinal peristalsis. The smooth muscle cell cytoskeleton consists of proteins whose primary function is to serve as a structural framework that surrounds and supports the contractile apparatus of actin and myosin filaments in the body of the smooth muscle cell. Nemeth et al.[71] studied the distribution of cytoskeleton in the smooth muscle of HD bowel by means of immunohistochemistry and found that dystrophin, vinculin, and desmin immunoreactivity was either absent or weak in the smooth muscle of aganglionic bowel, whereas it was moderate to strong in the smooth muscle of normal bowel and ganglionic bowel from patients with HD. Neural cell adhesion molecule (NCAM) is a cell surface glycoprotein involved in cell–cell adhesion during development that has been suggested to play an important role in development and maintenance of the neuromuscular system.[72–74] NCAM is present in the innervation of normal infant bowel and, less densely, in some components of the enteric smooth muscle. Contradictory results have been published regarding the NCAM expression in the smooth muscle of aganglionic bowel. Kobayashi et al.[56] have described a lack of expression of NCAM in the muscularis propria of the aganglionic bowel compared with the ganglionic segment, whereas Romanska et al.[75] have found an increase in the NCAM expression in muscle, particularly in the muscularis mucosae. Anyhow, both authors agree that there is a strong expression of NCAM in the hypertrophic nerve trunks from the aganglionic segment.

Extracellular matrix

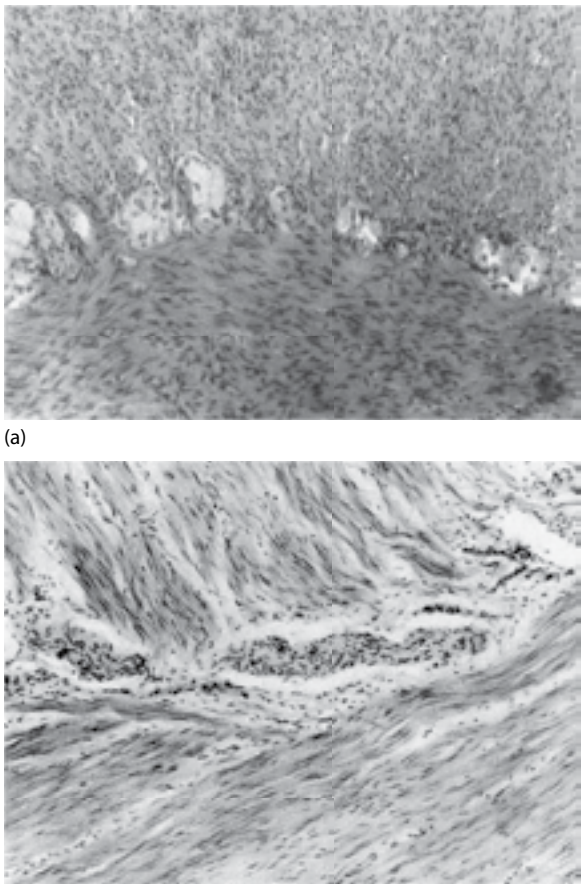
Although extracellular matrix (EM) abnormalities have been described mainly related to the pathogenesis of HD,

they could also have an influence on its pathophysiology. The lethal spotted mouse, an animal model that develops aganglionosis in its distal bowel, displays an abnormal distribution of EM components including laminin, collagen type IV, glycosaminoglycans, and proteoglycans in the smooth muscle layer.[76,77] Parikh et al.[78] have demonstrated that the laminin concentration in aganglionic bowel was twice as high as in the normoganglionic bowel of HD and three times higher than in an age-matched control. Moreover, by means of immunohistochemistry, they found an uneven distribution of laminin and collagen type IV in the muscularis propria of aganglionic bowel, being more intensely expressed in the circular layer than in the longitudinal layer.[79] The same authors have described that EM components tenascin and fibronectin are more intensely expressed in aganglionic bowel from HD.[79] Moreover, Soret et al. demonstrate that animals with excess collagen VI develop HD-like disease due to decreased enteric neural crest-derived cell (ENCDC) migration. The inhibitory effect of collagen VI on ENCDC migration may partially explain why children with Down's syndrome have an increased risk of HD, since collagen VI genes are on chromosome 21.[80]

PATHOLOGY

The characteristic gross pathological feature in HD is dilation and hypertrophy of the proximal colon with abrupt or gradual transition to narrow distal bowel (Figure 67.1). Although the degree of dilation and hypertrophy increases with age, the cone-shaped transitional zone from dilated to narrow bowel is usually evident in the newborn.

Figure 67.1 Typical gross pathology in HD, with transitional zone at rectosigmoid level.



(a)

(b)

Figure 67.2 **(a)** Auerbach's plexus, containing ganglion cells. **(b)** Hypertrophied nerve trunks in rectal biopsy from a patient with HD.

Histologically, HD is characterized by the absence of ganglionic cells in the myenteric and submucous plexuses, and the presence of hypertrophied nonmyelinated nerve trunks in the space normally occupied by the ganglionic cells (Figure 67.2). The aganglionic segment of bowel is followed proximally by a hypoganglionic segment of varying length. This hypoganglionic zone is characterized by a reduced number of ganglion cells, nerve fibers in myenteric and submucous plexuses, as well as disorganized and reduced numbers of ICCs.

DIAGNOSIS

The diagnosis of HD is usually based on clinical history, radiological studies, anorectal manometry, and in particular histological examination of the rectal wall biopsy specimens.

Clinical features

Of all cases of HD, 80%–90% produce clinical symptoms and are diagnosed during the neonatal period. Delayed passage of meconium is the cardinal symptom in neonates with HD.

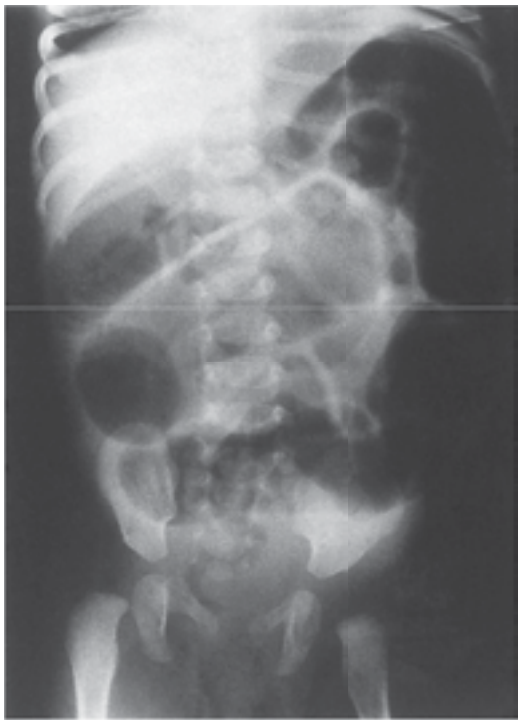
Figure 67.3 A 2-day-old infant with marked abdominal distention and failure to pass meconium. SRB confirmed HD.

Over 90% of affected patients fail to pass meconium in the first 24 hours of life. The usual presentation of HD in the neonatal period is with constipation, abdominal distension, and vomiting during the first few days of life (Figure 67.3). About one-third of the babies with HD present with diarrhea. Diarrhea in HD is always a symptom of enterocolitis, which remains the commonest cause of death. Enterocolitis may resolve with adequate therapy, or it may develop into a life-threatening condition, the toxic megacolon, characterized by the sudden onset of marked abdominal distension, bile stained vomiting, fever, and signs of dehydration, sepsis, and shock. Rectal examination or introduction of a rectal tube results in the explosive evacuation of gas and foul-smelling stools. In older children, the main symptom is persistent constipation and chronic abdominal distension.

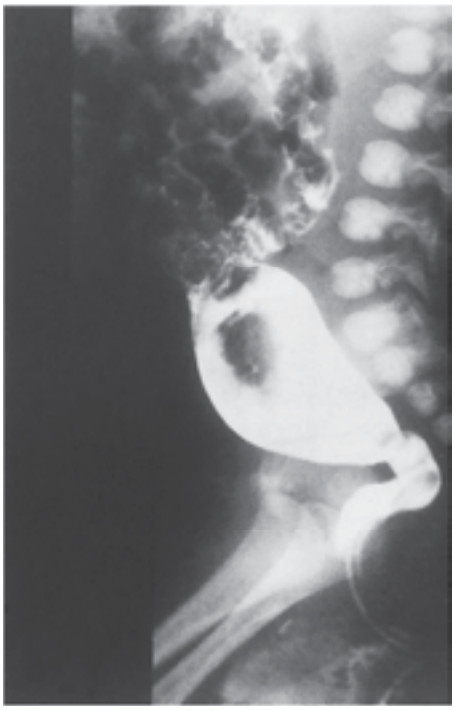
Radiological diagnosis

Plain abdominal films in a neonate with HD will show dilated loops of bowel with fluid levels and airless pelvis. Occasionally, one may be able to see a small amount of air in the undistended rectum and dilated colon above it raising the suspicion of HD (Figure 67.4a). Plain abdominal radiographs obtained from patients with TCA may show characteristic signs of ileal obstruction with air fluid levels or simple gaseous distension of small intestinal loops.

In patients with enterocolitis complicating HD, plain abdominal radiography may show thickening of the bowel wall with mucosal irregularity or a grossly dilated colon loop, indicating toxic megacolon. Pneumoperitoneum may be found in those with perforation. Spontaneous perforation of the intestinal tract has been reported in 3% of patients with HD.[81]



(a)



(b)

Figure 67.4 HD. **(a)** Abdominal radiograph in a 4-day-old infant showing marked dilation of large and small bowel loops. Note gas in undilated rectum. **(b)** Barium enema in this patient reveals transitional zone at sigmoid level.

Barium enema performed by an experienced radiologist using careful technique should achieve a high degree of reliability in diagnosing HD in the newborn. It is important that the infant should not have rectal washouts or even digital examinations prior to barium enema, as such interference

Figure 67.5 Delayed 24-hour film in lateral position showing barium retention with accentuated transition at splenic fixture in a 10-day-old baby.

Figure 67.6 Enterocolitis complicating HD. Spasm in rectosigmoid shown in barium enema, with fine mucosal ulceration and mucosal edema giving cobblestone appearance.

may distort the transitional zone appearance and give a false-negative diagnosis. A soft rubber catheter is inserted into the lower rectum and held in position with firm strapping across the buttocks. A balloon catheter should not be used due to the risk of perforation and the possibility of distorting a transitional zone by distension. The barium should be injected slowly in small amounts under fluoroscopic control with the baby in the lateral position. A typical case of HD will demonstrate flow of barium from the undilated rectum through a cone-shaped transitional zone into dilated colon (Figure 67.4b). Some cases may show an abrupt transition between the dilated proximal colon and the distal aganglionic segment, leaving the diagnosis in little doubt.

In some cases, the findings on the barium enema are uncertain, and a delayed film at 24 hours may confirm the diagnosis by demonstrating the retained barium and often accentuating the appearance of the transitional zone (Figure 67.5). In the presence of enterocolitis complicating HD, a barium enema can demonstrate spasm, mucosal edema, and ulceration (Figure 67.6)

In TCA, the contrast enema is not pathognomic and may not provide a definitive diagnosis. The colon in TCA is of normal caliber in 25%–77% of cases.[1,82]

Anorectal manometry

In the normally innervated bowel, distension of the rectum produces relaxation of the internal sphincter rectosphincteric reflex. In normal persons, upon distending the rectal balloon with air, the rectum immediately responds with a transient rise in pressure lasting 15–20 seconds; at the same time, the internal sphincter rhythmic activity is depressed or abolished, and its pressure falls by 15–20 cm, the duration of relaxation coinciding with the rectal wave (Figure 67.7).

In patients with HD, the rectum often shows spontaneous waves of varying amplitude and frequency in the resting phase. The internal sphincter rhythmic activity is more pronounced. On rectal distension, with an increment of air, there is complete absence of internal sphincter relaxation. Both term infants and premature babies have been shown to exhibit a well-developed recto-anal inhibitory reflex (RAIR) and anorectal pressures.[83] In the presence of a RAIR in children of under 1 year of age, HD is very unlikely. However, the specificity and positive predictive value of ARM for the diagnosis of HD are inferior to those of rectal suction biopsy. ARM may be a useful investigation in patients where a histologic specimen is inadequate and/or functional constipation is most likely diagnosed. Failure to detect the rectosphincteric reflex in premature and term infants is believed to be due to technical difficulties and not to immaturity of ganglion cells. Light sedation particularly in infants and small children may overcome technical difficulties encountered in this age group.

Rectal biopsy

The diagnosis of HD is confirmed on examination of rectal biopsy specimens. A correctly executed rectal biopsy procedure should involve sampling a segment of rectal wall 2 cm

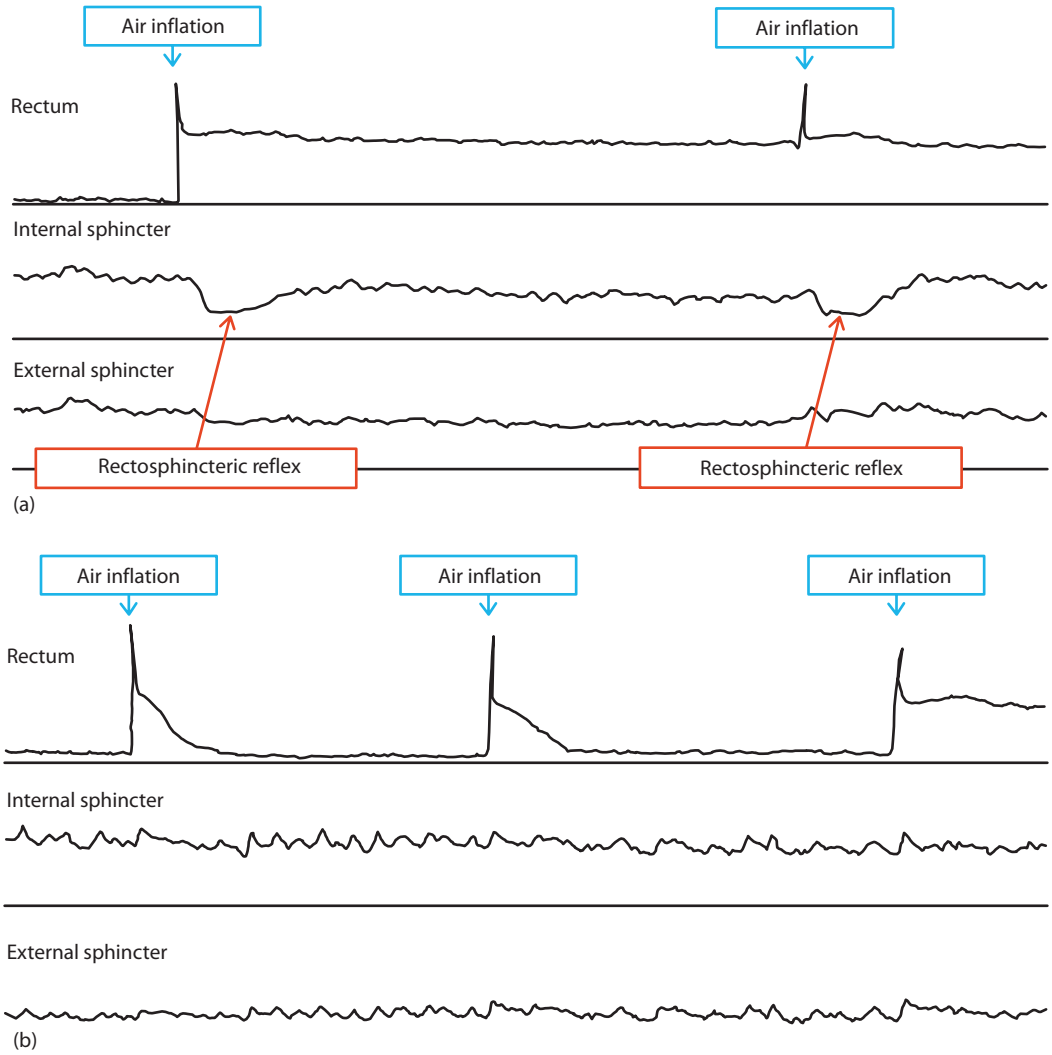


Figure 67.7 Anorectal manometry. **(a)** Normal rectosphincteric reflex on rectal balloon inflation. **(b)** Absence of rectosphincteric reflex and marked internal sphincter rhythmic activity in a patient with HD.

proximal to the dentate line along the posterior wall of the rectum. A biopsy taken too distally may collect a specimen from the physiologically aganglionic region erroneously suggesting the presence of HSCR, whereas a biopsy taken too proximally (i.e., over 4 cm) may miss very short segment of HSCR.[84]

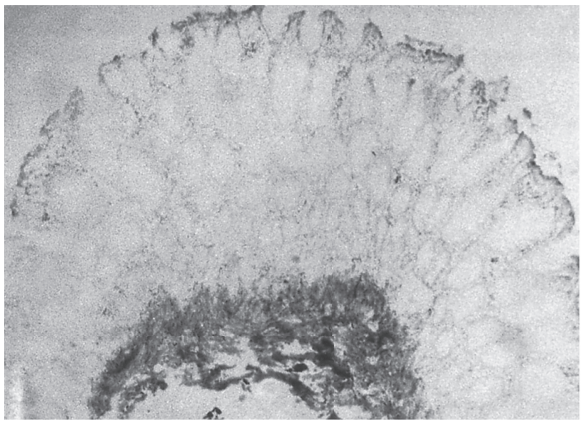
It is also important to bear in mind that recent enemas causing mucosal edema may influence the quality of the specimens; and also a poor technique such as incorrect placement of the biopsy system, and low pressure may contribute to inadequate biopsy specimens; in addition improper techniques like incorrect placement of the biopsy system and inadequate pressure all contribute to inadequate biopsies as well.

The introduction of histochemical staining (IHC) technique for the detection of AChE activity in suction rectal biopsy (SRB) has resulted in a reliable and simple method for the diagnosis of HD.[85–87]

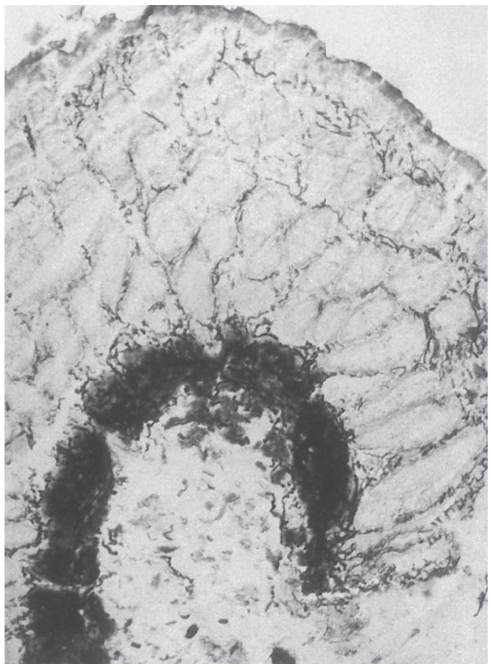
Full-thickness rectal biopsy is rarely indicated for the diagnosis of HD except in TCA. In normal persons, barely detectable AChE activity is observed within the lamina propria and muscularis mucosa, and submucosal ganglion cells stain strongly for AChE. In HD, there is a marked increase in AChE activity in lamina propria and muscularis, which is evident as coarse, discrete cholinergic nerve fibers stained brown to black (Figure 67.8).

Recently, calretinin staining has been introduced in the diagnostic of HD.[65] Calretinin, a calcium-binding protein that may function as a calcium sensor/modulator, is expressed by a subset of submucosal and myenteric ganglion cells, some of which project nerve terminals into the mucosa. Aganglionic segments completely lack calretinin immunoreactivity in enteric nerves (Figure 67.9).

Kapur et al.'s findings suggest that the sensitivity and specificity of calretinin IHC are equivalent, if not superior, to rapid AChE and that calretinin IHC may be informative when inadequate tissue is available to establish an H&E diagnosis. In fact, in their comparative study, unequivocal diagnosis or exclusion of HSCR by calretinin IHC alone was more accurate than rapid AChE alone, with no major errors



(a)



(b)

Figure 67.8 AChE staining of SRB. **(a)** Normal rectum showing minimal AChE staining in mucosa, lamina propria, and muscularis mucosae (×4). **(b)** HD characterized by marked staining of cholinesterase-positive nerves in the lamina propria and muscularis mucosae (×40).

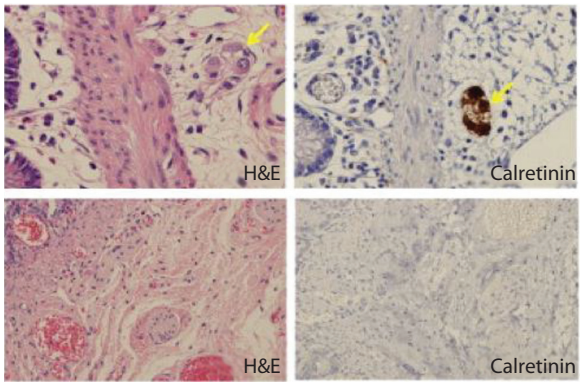


Figure 67.9 Calretinin staining of SRB.

and fewer equivocal readings.[88] Moreover, calretinin staining decreased the rate of inconclusive results and increased the likelihood of a confirmed diagnosis. On the other hand, a number of potential false-positive results described in the literature raise some concern for potential overtreatment, if calretinin is used alone.[89] However, in general, most of the results are in agreement with previous studies and argue for the addition of calretinin to the routine repertoire of stains used to diagnosis HSCR.[90]

In TCA, AChE activity in SRBs presents an atypical pattern, different from the classic one. Positive AChE fibers can be found in the lamina propria as well as the muscularis mucosae. However, cholinergic fibers present a lower density than in classical HD.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes other causes of a lower intestinal obstruction in newborns, including intestinal atresia, meconium ileus, meconium peritonitis, meconium plug, small left colon syndrome, and imperforate anus.

Table 67.4 gives the list of common differential diagnoses. Colonic atresia gives similar plain film findings to HD but is readily excluded with barium enema showing complete mechanical obstruction. Distal small bowel atresia shows gross distension of the bowel loop immediately proximal to the obstruction with the widest fluid level in it.

In meconium ileus, the typical mottled thick meconium may be seen. Also, clear, sharp fluid levels are not a feature in erect or lateral decubitus views. However, HD can sometimes simulate meconium ileus in plain films and may give equivocal findings on Gastrografin or barium enema.

Meconium plugs obstructing the colon can present as HD with strongly suggestive history and plain films. Small left colon syndrome is associated with maternal diabetes and presents with marked distension proximal to narrowed descending colon, and simulates HD at the left colonic flexure. These two conditions usually resolve with Gastrografin enema, but a minority of these cases will actually have Hirschsprung's, which should be excluded clinically. In both of these conditions, the rectum has a greater diameter than the sigmoid colon.

Table 67.4 Differential diagnosis of HD

Neonatal bowel obstruction
Colonic atresia
Meconium ileus
Meconium plug syndrome
Small left colon syndrome
Malrotation
Low anorectal malformation
Intestinal motility disorders/pseudo-obstruction
Necrotizing enterocolitis
Medical causes: sepsis, electrolyte abnormalities, drugs, hypothyroidism, etc.

In HD, on the other hand, the rectum has a diameter smaller than the sigmoid colon. Failure to completely evacuate the barium on a 24-hour delayed film is also suggestive of HD.

MANAGEMENT

Once the diagnosis of HD has been confirmed by rectal biopsy examination, the infant should be prepared for surgery. If the newborn has enterocolitis complicating HD, correction of dehydration and electrolyte imbalance by infusion of appropriate fluids will be required, as well as antibiotics coverage. It is essential to decompress the bowel as early as possible in these babies. Deflation of the intestine may be carried out by rectal irrigations with saline via a large catheter located high in the rectum or descending colon. Some babies may require "leveling" colostomy. The level at which the colostomy is placed is determined by rapid frozen sections of seromuscular biopsies obtained from the colon during the operation. One must be assured that there are normal ganglion cells at the site of the proposed colostomy.

In recent years, the vast majority of cases of HD are diagnosed in the neonatal period. Many centers are now performing one-stage pull-through operations in the newborn with minimal morbidity rates and encouraging results. The advantages of operating on the newborn are that the colonic dilation can be quickly controlled by washouts, and at operation, the caliber of the pull-through bowel is near normal, allowing for an accurate anastomosis that minimizes leakage and cuff infection. A number of different operations have been described for the treatment of HD. The four most commonly used operations are the rectosigmoidectomy developed by Swenson and Bill, the retrorectal approach developed by Duhamel, the endorectal procedure developed by Soave, and deep anterior colorectal anastomosis developed by Rehbein.[91] The basic principle in all these procedures is to bring the ganglionic bowel down to the anus. The long-term results of any of these operations are satisfactory if they are performed correctly. Recently, a number of investigators have described and advocated a variety of one-stage pull-through procedures in the newborn using minimally invasive laparoscopic techniques. More recently, a transanal endorectal pull-through (TERPT) operation performed without opening the abdomen has been used with excellent results in rectosigmoid HD.

Transanal one-stage endorectal pull-through operation

Over 80% of patients with HD have rectosigmoid aganglionosis. A one-stage pull-through operation can be successfully performed in these patients using a transanal endorectal approach without opening the abdomen. This procedure is associated with excellent clinical results and permits early postoperative feeding, early hospital discharge, no visible scars, and low incidence of enterocolitis.[92–95] The author prefers TERPT operation in patients with classical segment rectosigmoid HD.

PREOPERATIVE MANAGEMENT

A good barium enema study is essential for this technique. A typical case of rectosigmoid HD will demonstrate flow of barium from undilated rectum through a cone-shaped transition zone into dilated sigmoid colon (Figure 67.4b). Once the diagnosis of HD is confirmed by SRB, the newborn is prepared for surgery. Rectal irrigations are carried out twice a day for 2–3 days prior to surgery. I.V. gentamicin and metronidazole are started on the morning of operation.

OPERATIVE TECHNIQUE

The patient is positioned on the operating table in the lithotomy position. The legs are strapped over sandbags. A Foley catheter is inserted into the bladder. A Denis–Browne retractor or anal retractor is placed to retract perianal skin. The rectal mucosa is circumferentially incised using the cautery with a fine tipped needle, approximately 5 mm from the dentate line, and the submucosal plane is developed. The proximal cut edge of the mucosal cuff is held with multiple fine silk sutures, which are used for traction (Figure 67.10). The endorectal dissection is then carried proximally, staying in the submucosal plane.

When the submucosal dissection has extended for about 3 cm, the rectal muscle is divided circumferentially, and the full thickness of the rectum and sigmoid colon is mobilized out through the anus. This requires division of rectal and sigmoid vessels, which can be done under direct vision using cautery.

When the transition zone is encountered, full-thickness biopsy sections are taken, and frozen section confirmation of ganglion cells is obtained. The rectal muscular cuff is split longitudinally either anteriorly or posteriorly. The colon is then divided several centimeters above the most proximal normal biopsy site, and a standard Soave–Boley anastomosis is performed (Figure 67.8). No drains are placed. The patient is started on oral feeds after 24 hours and discharged home on the third postoperative day. Digital rectal examination is performed 2 weeks after the operation. Routine rectal dilatation is not performed unless there is evidence of a stricture.

LAPAROSCOPIC-ASSISTED PULL-THROUGH

Despite the fact that many of the benefits of the pull-through procedure can be attained by transanal pull-through alone, significant advantages are realized by performing the laparoscopic dissection.[96] Prior to the irreversible step of endorectal dissection, laparoscopy allows one to verify the presence of ganglion cells in the proximal colon pedicle by seromuscular biopsy. In cases of total colon aganglionosis, a different type of pull-through operation or ostomy might be considered. In addition, laparoscopic mobilization of the intra-abdominal segment increases the mobility of the

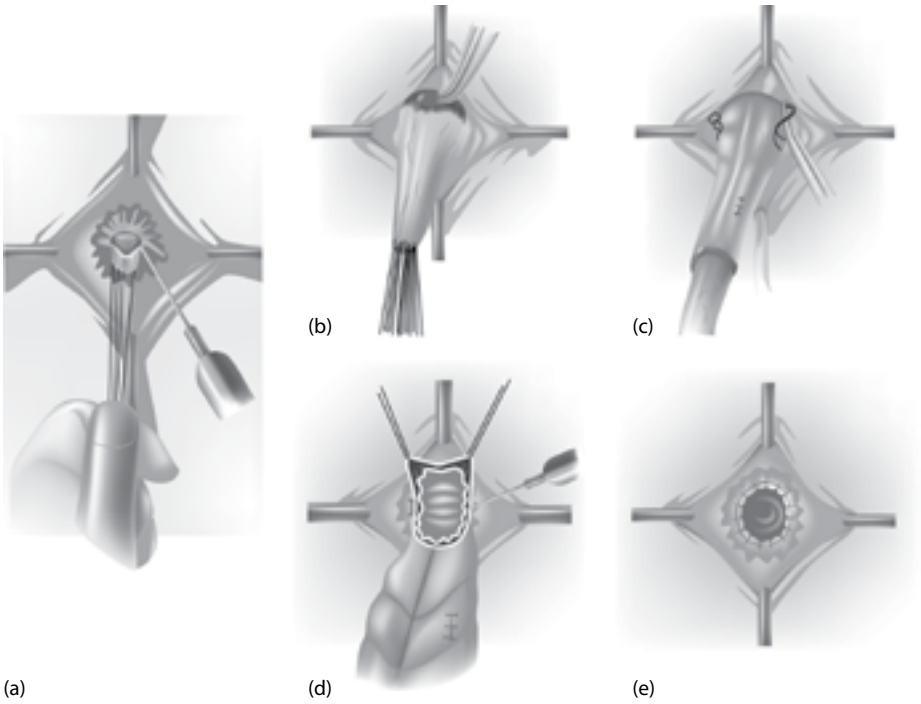

Figure 67.10 TERPT. **(a)** Rectal mucosa is circumferentially incised using the needle-tip cautery approximately 5 mm above the dentate line, and submucosa plane is developed. **(b)** When the submucosal dissection is extended proximally for about 3 cm, the muscle is divided circumferentially, and the full thickness of the rectum and sigmoid colon is mobilized out through the anus. **(c)** On reaching the transition zone, full-thickness rectal biopsies are taken for frozen section to confirm ganglion cells. **(d)** Colon is divided several centimeters above the most proximal biopsy site. **(e)** A standard Soave–Boley anastomosis is performed.

rectum and makes the endpoint of the endorectal dissection more definitive.[97]

Initially, three ports (Figure 67.11) are placed to visualize the transition zone and to perform biopsies for histologic leveling. A window is then made between the colon and superior rectal vessels, and distal dissection of the aganglionic colon is then performed circumferentially, keeping close to the colon wall, carefully preserving the mesenteric blood supply to the rectum. Blunt and sharp dissection of avascular plane posterior to the rectum follows. Anteriorly, the rectum is dissected for about 1 to 2 cm below the peritoneal reflection. It is important to avoid extensive lateral dissection, where damage to the nervi erigentes can result. Proximal mesenteric dissection of the colon pedicle with careful preservation of the marginal artery depends on the extent of the aganglionic segments; some patients require sigmoid colon mobilization or division of the lateral colonic fusion fascia up to the splenic flexure. After the endoscopic dissection of the colon and rectum has been completed, the pneumoperitoneum is released and the instruments removed, and the procedure is completed with an endorectal transanal pull-through.

Once, the anastomosis of the proximal ganglionated colon with the anorectal cuff is completed, reinsufflation for pneumoperitoneum can be performed to inspect the colon pedicle for twisting or potential internal herniation.[98]

The most frequent early complications after laparoscopically assisted endorectal pull-through (LAPT) include enterocolitis and chronic diarrhea. These problems often respond to medical management. Other less frequent problems include anastomotic leaking and bleeding, which are associated with technical error.

A recently conducted meta-analysis that included 159 patients after LAPT and 248 patients after TERPT did not find any evidence to suggest a higher rate of enterocolitis, incontinence, or constipation following TERPT compared with LAPT. Further long-term comparative studies and multicenter data pooling are needed to determine whether a laparoscopically assisted approach offers any advantages over a purely transanal approach to HD.[99]

COMPLICATIONS

Early postoperative complications that can occur after any type of pull-through operation include wound infections, anastomotic leak, anastomotic stricture, retraction or necrosis of the neorectum, intestinal adhesions, and ileus. Late complications include constipation, enterocolitis, incontinence, anastomotic problems, adhesive bowel obstruction, and urogenital complications.

Anastomotic leak

The most dangerous early postoperative complication following the definitive abdominoperineal pull-through procedure is leakage at the anastomotic suture line. Factors that are responsible for anastomotic leak include ischemia of the distal end of the colonic pull-through segment, tension on the anastomosis, incomplete anastomotic suture lines, and inadvertent rectal manipulation. If a leak is recognized in a patient without a colostomy, it is imperative to perform a diverting colostomy promptly, to administer intravenous antibiotics, and to irrigate the rectum with antibiotic solution a few times daily. Delay in establishing fecal diversion is likely to result in an extensive pelvic abscess, which may require laparotomy and transabdominal drainage.

Retraction of pull-through

Retraction of a portion or all of the colonic segment from the anastomosis can occur and is usually seen within 3 weeks of the operation. Evaluation under general anesthesia is generally necessary. In occasional patients, resuturing the anastomosis may be feasible transanally. For those with separation of less than 50% of the anastomosis but with adequate vascularity of the colon, a diverting colostomy for approximately 3 months is necessary. For patients with wide separation at the anastomosis, early transabdominal reconstruction of the pull-through is recommended.

Perianal excoriation

Perianal excoriation occurs in nearly half of the patients undergoing the pull-through procedure, but generally resolves within 3 months with local therapy and resolution of diarrhea. It is helpful to begin placing a barrier cream on the perianal skin promptly after the operation and to continue after each movement for the first few weeks. Resolution of diarrhea will often hasten the clearance of perianal skin irritation.

Enterocolitis

Hirschsprung's associated enterocolitis (HAEC) is a significant complication of HD both in the pre- and postoperative periods.[81,100] HAEC can occur at any time from the neonatal period onward to adulthood and can be independent of the medical management and surgical procedure performed. The incidence of enterocolitis ranges from 20% to 58%.[81,100] Fortunately, the mortality rate has declined over the last 30 years from 30% to 1%. This decrease in mortality is related to earlier diagnosis of HD and enterocolitis, rectal decompression, appropriate vigorous resuscitation, and antibiotic therapy. It has been reported that routine postoperative rectal washouts decrease both the incidence and the severity of the episodes of enterocolitis following definitive surgery. In episodes of recurrent enterocolitis, which can develop in up to 56% of patients, anal dilatations have been recommended. However, prior to commencing a treatment regime, a contrast enema should be performed to rule out a mechanical obstruction. Patients with a normal rectal biopsy may require a sphincterotomy.

Constipation

Constipation is common after definitive repair of HD and can be due to residual aganglionosis and high anal tone. Repeated and forceful anal dilations of botulin toxin injection into the sphincter under general anesthesia may resolve the problem. In some patients, internal sphincter myectomy may be needed. In patients with scarring, stricture, or intestinal neuronal dysplasia proximal to aganglionic segment, treatment consists of treating the underlying cause.

Soiling

Soiling is fairly common after all types of pull-through operations, its precise incidence primarily dependent on how assiduously the investigator looks for it. The reported incidence of soiling ranges from 10% to 30%.[95] The attainment of normal postoperative defecation is clearly dependent on intensity of bowel training, social background, and respective intelligence of the patients. Mental handicap, including Down's syndrome, is invariably associated with long-term incontinence.[101] Those patients with preoperative

enterocolitis would also seem to have a marginally higher long-term risk of incontinence. In some patients in whom soiling is intractable and a social problem, a Malone procedure may be needed to stay clean.

LONG-TERM OUTCOME

The vast majority of patients treated with any one of the standard pull-through procedures achieve satisfactory continence and function with time.[82,101–103]

FUTURE THERAPIES

Our growing understanding of what failures of normal development of ENS result in HD coupled with our progress in understanding normal gut development and motility has led to an expanding field of research into developing novel therapies for HSCR.

Stem cell transplantation using laboratory-cultured neural stem cells (NSCs) to colonize aganglionic intestine and restore intestinal motility has been proposed as a treatment for HSCR.[15]

Several potential sources of cells capable of generating enteric neurons have been investigated for ENS replenishment including CNS-derived neural stem cells (NSCs), embryonic enteric neural crest cells, postnatal ENS progenitor cells, and amnion fluid–derived stem cells.[105]

Recently, Fattahi et al. demonstrated the efficient derivation and isolation of ENS progenitors from human pluripotent stem cells, and their further differentiation into functional enteric neurons. They showed that ENS precursors derived in vitro are capable of targeted migration in the developing chick embryo and extensive colonization of the adult mouse colon.

In vivo engraftment and migration of hPSC-derived ENS precursors rescues disease-related mortality in HSCR mice ($EDNRB^{s\text{-}l/s\text{-}l}$). Finally, EDNRB-null mutant ENS precursors enable modelling of HSCR-related migration defects.[106]

Their work presents a powerful strategy to access human ENS lineages for exploring the ENS in human health and disease and for developing novel cell- and drug-based therapies for HSCR.

In conclusion, transplanted ENS may contribute to functional improvement directly by repopulating the aganglionic gut with implanted neurons and restoring neural circuits; it may also release trophic factors or neurotransmitters that can improve intestinal contractile function, and finally it can open a new field in the treatment of HD.

Anorectal anomalies

ANDREA BISCHOFF AND ALBERTO PEÑA

ANORECTAL ANOMALIES

Anorectal anomalies present with a spectrum of defects; on the "good" side of the spectrum, we see patients with minor malformations that require minimal treatment with excellent results; on the other extreme of the spectrum, we find cases with complex defects, which represent a serious technical challenge and for whom the results in terms of bowel, urinary, and sexual function are not good despite accurate anatomic reconstruction. A newborn with an anorectal malformation may represent a surgical emergency related to intestinal obstruction and (or) due to severe associated urologic, gastrointestinal, or cardiac defects, which may require aggressive and efficient management. Other patients with these defects do not represent an emergency, because they have a fistula that allows intestinal decompression and they are born without serious associated abnormalities. In these cases, the repair of the defect can become an elective procedure or, if the baby is in good condition, can be definitively managed in the newborn period.

Frequency

Anorectal malformations occur with a frequency of approximately 1 in 4000 or 5000 newborns.[1–3]

Classification

Table 68.1 shows a classification that is anatomically based, and has prognostic and therapeutic implications.[4,5]

CLINICAL FEATURES AND DIAGNOSIS

Male defects

PERINEAL FISTULA

Patients with this defect have an abnormal communication between the rectum and the perineum (Figure 68.1), often with a "bucket-handle" malformation (Figure 68.2). The common anatomic feature is the fact that the intestinal opening is located anterior to the center of the sphincter mechanism, as demonstrated by electrical stimulation during the repair (Figure 68.3). We prefer to avoid terms such as *anterior ectopic anus*, as this opening is not really an anus as it has no pectinate line and it is not surrounded by a sphincter. We believe the term *perineal fistula* is a more accurate one. The fistula can occur anywhere along the median raphe. These defects can be treated primarily without a protective colostomy. Most of the time, the patient is able to pass small amounts of meconium through the orifice in the perineum. Sometimes it takes a few hours before the baby passes meconium. The presence of a prominent midline epithelial tag below which one can pass an instrument (bucket-handle malformation) is considered pathognomonic of this defect (Figure 68.2). Many times, one sees a midline raphe subepithelial fistula that looks like a black (meconium) or white (mucus) ribbon, which is also evidence of this type of defect (Figure 68.1). Otherwise, the patients have a perineum with signs of *good prognosis*, which include a prominent midline groove and a noticeable anal dimple. The diagnosis is made by clinical inspection, and usually, no radiologic studies are necessary. The chance of having an associated genitourinary defect is extremely low. The patient's spine should be screened for an associated, albeit rare, tethered cord.

RECTOURETHRAL BULBAR AND RECTOURETHRAL PROSTATIC FISTULAS

These two types of defects are similar from a clinical point of view. However, generally speaking, patients with rectourethral bulbar fistula are more likely to have a "good-looking" perineum (Figure 68.4); this means having a prominent midline groove and anal dimple.

In cases of prostatic fistula, the chances of having a short sacrum and a flat perineum (Figure 68.5) increase. The rectum can open into the bulbar urethra (Figure 68.6) or into the prostatic urethra (Figure 68.7). Both rectum and

urethra have a common wall located above the fistula site, which is longer in the case of bulbar fistula and shorter in the prostatic type. The neonatal nurse may notice that the baby is passing meconium through the urethra. A cross-table lateral film, with the patient in the prone position and the pelvis elevated, is rarely necessary.[6] Figure 68.8 shows a rectum very close to the perineal skin, and Figure 68.9 shows a higher rectum. The chances of a rectourethral fistula case being associated with urological problems vary from 25% in cases of urethral bulbar fistula to 66% in cases of urethral prostatic fistula. These newborns need a diverting colostomy.

Figure 68.5 Flat bottom.

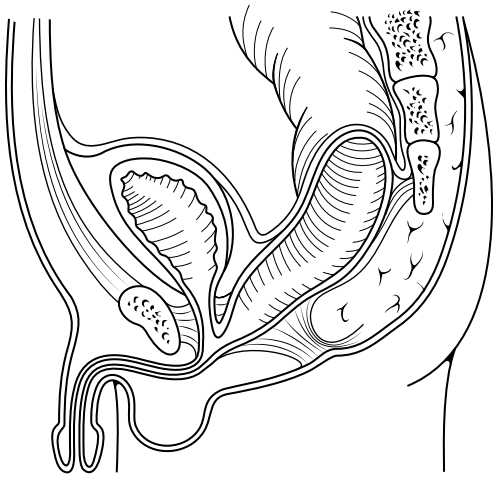

Figure 68.6 Rectourethral bulbar fistula—sagittal view.

RECTOVESICAL (BLADDER NECK) FISTULA

This defect accounts for approximately 10% of all anorectal defects in males. The rectum opens into the bladder neck in a "T" fashion (Figure 68.10). Frequently, the entire pelvis of these babies seems to be hypodeveloped. It is also common for these patients to have poor sphincter development, and the perineum looks rather flat in most patients (Figure 68.5), although some patients with these defects may have a good-looking perineum (Figure 68.4) with a midline groove and a prominent anal dimple. The frequency of associated urological anomalies in this specific defect is very high (up to 90%),[7] and therefore, a urologic workup is mandatory. A cross-table

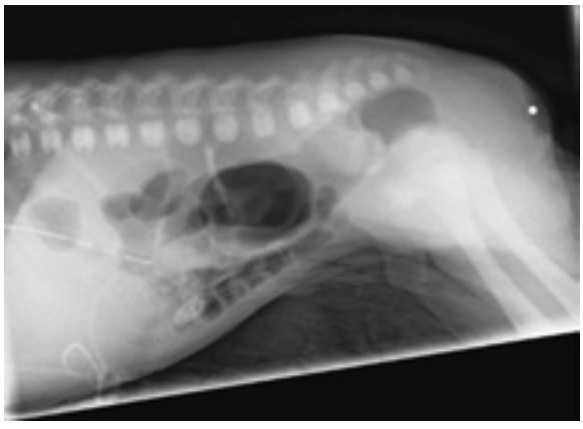

Figure 68.9 Cross-table lateral film of a rectum that is greater than 2 cm from the perineal skin representing a likely rectourethral or bladder neck fistula.

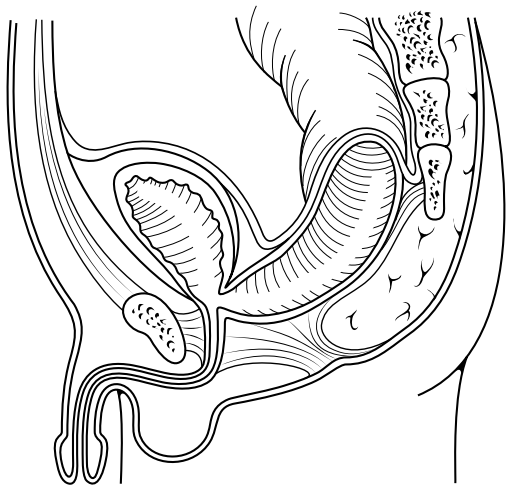

Figure 68.10 Rectovesical (bladder neck) fistula sagittal view.

lateral film, with the patient in prone position and with the pelvis elevated, shows an image consistent with air much higher than the pubococcygeus line (Figure 68.9). The neonatal nurses may note that the baby is urinating meconium. Manifestations of intestinal obstruction will become evident during the first 12–24 hours. In addition to these symptoms, the baby may show symptoms consistent with acidosis and sepsis secondary to an obstructive uropathy. These patients require a colostomy. They will require an abdominal approach (laparoscopic or laparotomy) during the definitive repair, in addition to the posterior sagittal approach.

IMPERFORATE ANUS WITHOUT FISTULA

In this type of defect, the rectum is really blind and is usually located at the level of the bulbar urethra. Even when there is no communication between rectum and urethra, the wall that separates both of them is long and has no surgical plane of separation. This defect is uncommon, but it has a good sphincter mechanism, and therefore, most of the time, the perineum is a good-looking one. The frequency of this defect is approximately 5% of male defects.[8] It is common to read reports indicating that these defects occur more often. We believe that those reports reflect diagnostic errors, consecutive to an inadequate radiologic study; a distal colostogram that is not done properly will give an incorrect assessment of "no fistula." A successful colostogram requires the injection of contrast material through the mucous fistula (distal bowel) of the colostomy, under enough hydrostatic pressure so as to demonstrate the passage of contrast material through the fistula into the urethra.[9] The rectum in all types of malformations is surrounded by voluntary muscle (Figures 68.3, 68.6, 68.7, and 68.10), and the hydrostatic pressure must be high enough to overcome the tone of the muscle that is compressing it. It is interesting to note that out of all our cases of imperforate anus with no fistula, approximately half of them have Down syndrome. The other half is predominantly made up of patients with other syndromes. Also, in all of our Down syndrome patients with imperforate anus, 95% have no fistula, clearly pointing to a genetic relationship between the type of defect and Down syndrome.[10,11] These patients also require a newborn diverting colostomy. Chances for these patients to have an associated defect are low, except for those malformations frequently associated with Down syndrome.

RECTAL ATRESIA AND STENOSIS

This is a rare type of defect classically described as the one that is diagnosed by the nurse while passing the thermometer during the initial newborn physical examination. The reason for this is that these babies are born with a normal anal canal and have an atresia located about 1–2 cm above the anal verge. Above that, there is a dilated rectal pouch. Sometimes, the patient actually has a stenosis. The separation between the blind pouch and the anal canal may be by a very thin membrane, but more frequently, there is a thick fibrous septum 3–7 mm in length. These patients most frequently need a colostomy. The perineum looks normal. The sacrum is usually normal and the chances of associated defects are extremely low. All patients must have an anteroposterior (AP) film of the sacrum; a sacral defect is always associated with the presence of a presacral mass, which seems to occur more frequently in this malformation than in others. The presacral mass must be looked for by magnetic resonance imaging (MRI). The mass is usually a teratoma, dermoid, lipoma, anterior meningocele, or a combination of all. In addition, in cases with presacral mass, there is an associated tethered cord. These patients have all the necessary anatomical elements to become totally continent; the muscles are intact, and the anal canal has normal sensation. However, the presence of a presacral mass has a radical negative effect on the functional prognosis.

Female defects

CUTANEOUS (PERINEAL) FISTULA

This is the most benign defect seen in females, and it is equivalent to the same defect already described in males. The fistula site is located anywhere between the vestibule of the female genitalia and the center of the anal dimple (Figure 68.11). The entire fistula site is surrounded by skin,

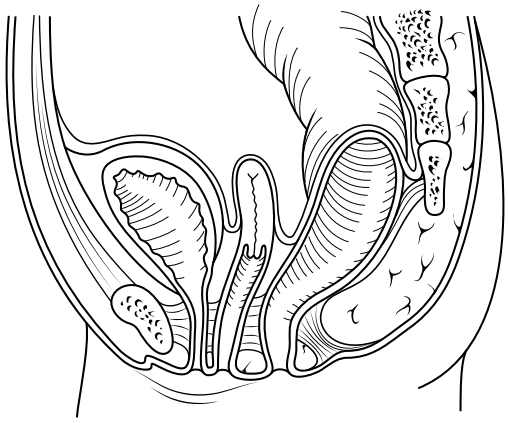

Figure 68.11 Perineal fistula in a female patient.

and therefore, it is also given the name of *cutaneous fistula*. The orifice is variable in size, and therefore, it may be sufficient for a full-bowel evacuation, or else it may require dilations to provide good bowel movements, until the main repair is done later in life. It is not uncommon to see older patients born with this malformation, which was never diagnosed. The patients suffer from severe constipation, which leads them to ask for a consultation. The defect is then diagnosed during the examination.

Our routine is to repair this malformation within the first 3 days of life, ideally when the patient is still passing meconium and before she starts being fed. Postoperatively, we keep the baby with nothing by mouth (NPO) receiving intravenous nutrition for 5 days after the repair.

These patients do not require a protective colostomy as part of their treatment. The most prominent anatomical feature in this type of defect is that the rectum and vagina are very close, although they do not share a common wall (Figure 68.11). Thus, the technical implication is that the rectum can be mobilized without risking injury to the vagina. Patients have otherwise normal sphincter mechanism and a normal sacrum. The incidence of associated defects (except for the presence of presacral mass) of the urinary tract or spine is very low.

VESTIBULAR FISTULA

This is the most frequent defect seen in females. The distal rectum opens into the vestibule, which is the space located immediately outside the hymen (Figure 68.12). The most notable anatomical feature in this defect is the presence of a very long common wall between rectum and vagina located above the fistula site (Figure 68.12). The vagina must be completely separated from the rectum in order to achieve good rectal mobilization and a tension-free repair. There is no surgical plane of separation between these two structures, and one must be carefully created. The fistula is usually represented by a short (5–15 mm) narrow rectal opening, which sometimes is not wide enough to decompress the bowel and requires dilatations if the surgeon is not proceeding with a newborn repair. Above that, one finds a normal rectum. Sometimes, the orifice is wide enough to allow a satisfactory decompression. The opening of a colostomy is the safest way to manage these girls, but an experienced surgeon can operate on this defect primarily without a colostomy if the baby is otherwise healthy. In such a case, we would operate in the newborn period and would keep the patient NPO receiving intravenous nutrition for 7 days after surgery. The incidence of associated urogenital malformations is 30%.[7] The sacrum is usually normal. The perineum of these babies shows a prominent midline groove and a very obvious anal dimple. Once in a while in this defect, we see a "poor-looking" perineum as well as short or very abnormal sacrum.

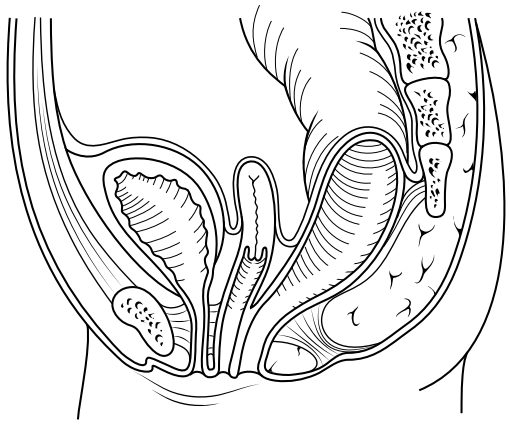

Figure 68.12 Vestibular fistula.

VAGINAL FISTULA

A true vaginal fistula is a very unusual defect. Less than 1% of females have this malformation. On the other hand, vaginal fistula is presented in the traditional literature as a relatively common defect. A recent review of the authors' own experience with reoperations in female patients showed 80 female patients operated on at other institutions with a diagnosis of rectovaginal fistula. During our reoperations, we got objective evidence indicating that none of these patients actually had rectovaginal fistulas. In fact, two-thirds of them had cloacas. The original surgeons were unaware of the correct diagnosis; they repaired the rectal component of the malformation and left the patient with a persistent urogenital sinus. The remaining one-third of the patients actually had vestibular fistulas, which was evidenced by the presence of the original fistula in the vestibule.[12] The importance of this observation is not only semantic; the group of patients that were born with cloacas were mislabeled as having rectovaginal fistulas, and the patients missed a great opportunity to have their entire malformation repaired during the first operation. The results of a second procedure are never as good as the first one. Furthermore, the patients with vestibular fistula were frequently erroneously subjected to an unnecessary abdominoperineal operation (designed to repair "high" malformations), and as a result, they suffer from fecal incontinence, consecutive to the resection of the rectosigmoid, which was part of the old endorectal abdominoperineal procedures. Therefore, it is very important to increase the index of suspicion for malformations such as cloaca and vestibular fistula, and to recognize that vaginal fistulas are almost nonexistent defects.

To make the diagnosis of a real rectovaginal fistula (Figure 68.13) it is necessary to perform a meticulous inspection of the genitalia, which is sometimes not easy in the newborn period due to edema of the labia. Patients with rectovaginal fistulas would show meconium coming from inside the vagina through the hymen. These babies may have a significant incidence of associated urological defects (around 70%).[7] If the rectum is connected to the vagina very high and the urethra and vagina are normal, that could be a rare indication for a laparoscopy in a female with anorectal malformation.

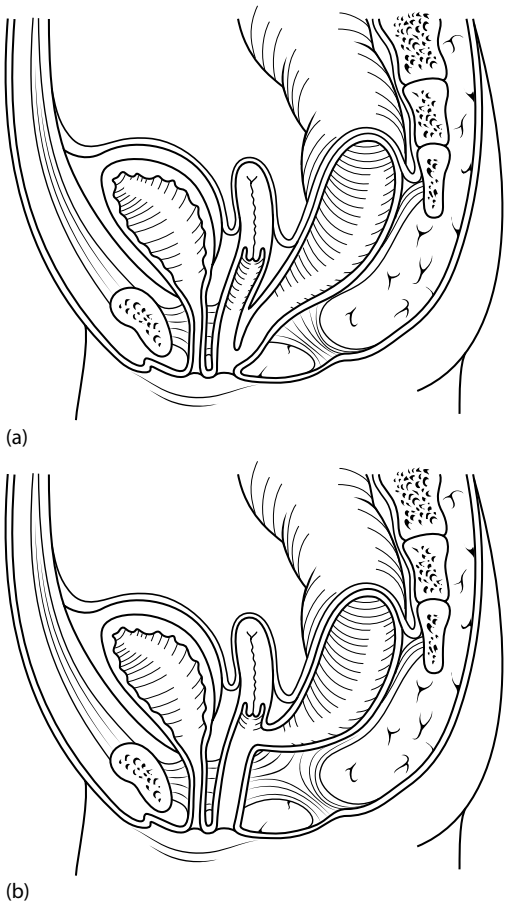

Figure 68.13 Vaginal fistula: **(a)** low; **(b)** high.

IMPERFORATE ANUS WITHOUT FISTULA

All that was written regarding this defect in males is valid regarding females, the only difference obviously being that the rectum shares a common wall with the vagina, not with the urethra.

RECTAL ATRESIA AND STENOSIS

This type of defect is identical to the one described in males, except that its frequency in females seems to be higher. The clinicians must always remember to screen for a presacral mass.

PERSISTENT CLOACA

This is the most complex anorectal malformation seen in females. It represents approximately 10% of the total number of anorectal defects. A cloaca is defined as the junction of the rectum, vagina, and urethra into a single common channel (Figure 68.14). Cloacas represent another spectrum by themselves. In other words, at one end of the spectrum one may find a rather benign, short-common-channel type of cloaca with good functional prognosis and no associated defects. At the other end of the spectrum, one can find a very complex defect with a very long common channel (3–8 cm length), with a very short vagina, severe associated obstructive uropathy, as well as very poor sacrum and poor

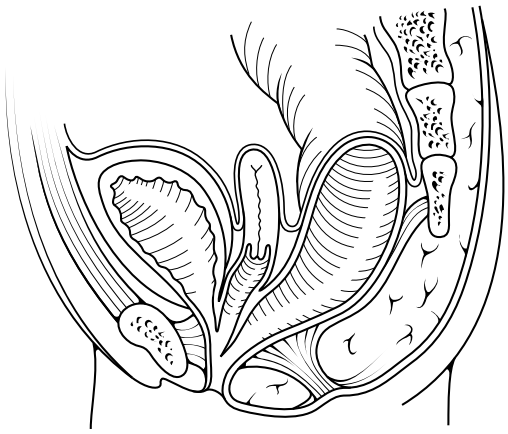

Figure 68.14 Persistent cloaca.

sphincter (Figure 68.15). The prognosis for this last type of case will be very poor for bowel and urinary control. The spectrum of cloacas includes many different types. One may see patients with a very dilated vagina, which becomes evident as a palpable abdominal mass and is called hydrocolpos. The dilated vagina usually causes urinary obstruction from compression of the ureterovesical junction at the trigone (Figure 68.16). A frequent finding is a double vagina and double uterus; in this type of case, the rectum may open at different levels in the midvaginal septum (Figure 68.17). The majority of these long-common-channel cloacas require an abdominal approach during the definitive repair, in addition to the posterior sagittal operation.[13]

The most important fact to remember in this type of defect is the high incidence of associated urinary tract obstruction (70%–90%).[7] Obstructive uropathy is the main cause of morbidity and even mortality in these patients.

The diagnosis of a cloaca is a clinical one. General practitioners, pediatricians, neonatologists, and pediatric surgeons must suspect this defect if they want to detect it and make an early diagnosis. A baby girl with an absent anus and small-looking genitalia must arouse suspicion for the presence of

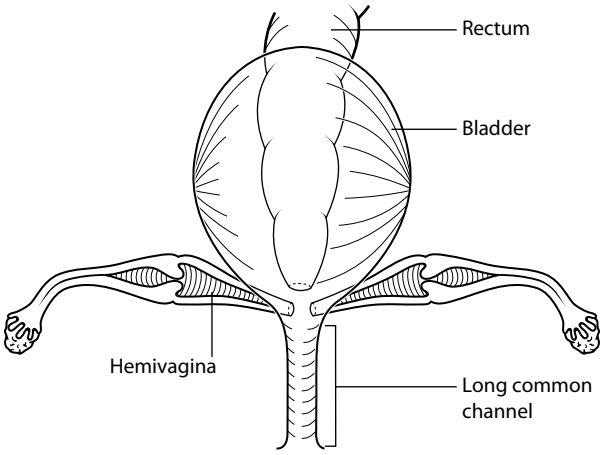

Figure 68.15 High cloaca with common channel of 5 cm.

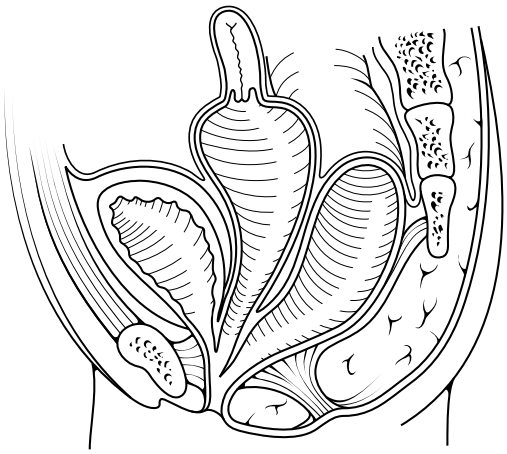

Figure 68.16 Cloaca with hydrocolpos.

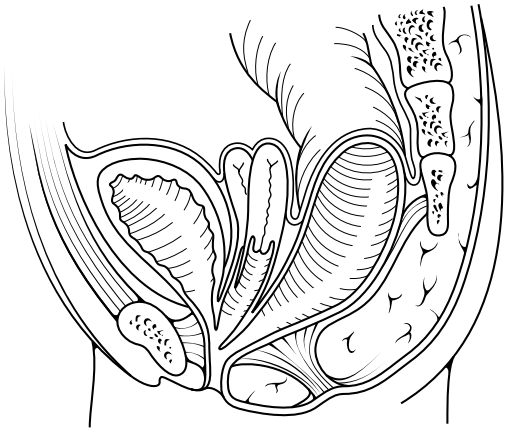

Figure 68.17 Duplicate Mullerian system.

a persistent cloaca (Figure 68.18). If one separates the labia minora, a single orifice becomes evident. These findings are pathognomonic for a cloaca. At that point, the priority in a newborn is the evaluation and treatment of the associated defects of the urinary tract. The external appearance of the perineum in these babies may vary. Sometimes, a poor-looking perineum is found, which means a flat bottom, a very poor midline groove, and almost absent anal dimple. Other times, one may find a cloaca with a good sphincter and a good sacrum. A patient with a cloaca always needs a completely diverting colostomy. If a hydrocolpos is present, the patient also needs a vaginostomy. Very rarely is a vesicostomy also needed. In addition to the mandatory urologic evaluation, in cases of cloacas, other associated malformations must be excluded, including tethered cord, cardiac defects, esophageal atresia, and spinal malformations.

In female patients, the diagnosis of the specific type of anorectal malformation is clinically obvious; a meticulous examination of the perineum and a good index of suspicion provide enough information to determine whether or not the patient has a perineal, vestibular, or vaginal fistula or a cloaca.

Figure 68.18 Cloaca, perineal appearance.

PREOPERATIVE CARE

Figures 68.19 and 68.20 show the decision-making algorithms for the initial management of newborns with anorectal malformations.

In approximately 90% of males, physical examination (perineal inspection) produces enough information to determine whether the patient needs a colostomy or not. The presence of a perineal subepithelial midline raphe fistula, a bucket-handle malformation, and any other type of anal orifice ectopically opening in the perineum are all considered evidence of a malformation traditionally known as "low," which can be treated during the newborn period with a simple anoplasty and without a protective colostomy. In cases of very ill babies, a series of anal dilatations may be enough to allow bowel decompression, leaving the anoplasty to be done later as an elective procedure. On the other hand, a flat bottom, or evidence of meconium in the urine, a very abnormal sacrum or spine, or other severe associated defects, is enough information to proceed with a protective colostomy. Four to eight weeks after the colostomy is done and provided the patient is growing and developing well, a radiological evaluation of the distal colon (high-pressure distal colostogram) is done to determine the specific type of malformation that the patient has and to decide the type of operation indicated; most of the time, it will consist in a posterior sagittal anorectoplasty. All these defects together represent approximately 90% of the entire group of anorectal defects in males. The remaining 10% have questionable, external, clinical evidence. In these cases, we recommend the cross-table lateral film with the patient in the prone position.[6] An intraluminal rectal bubble located above the

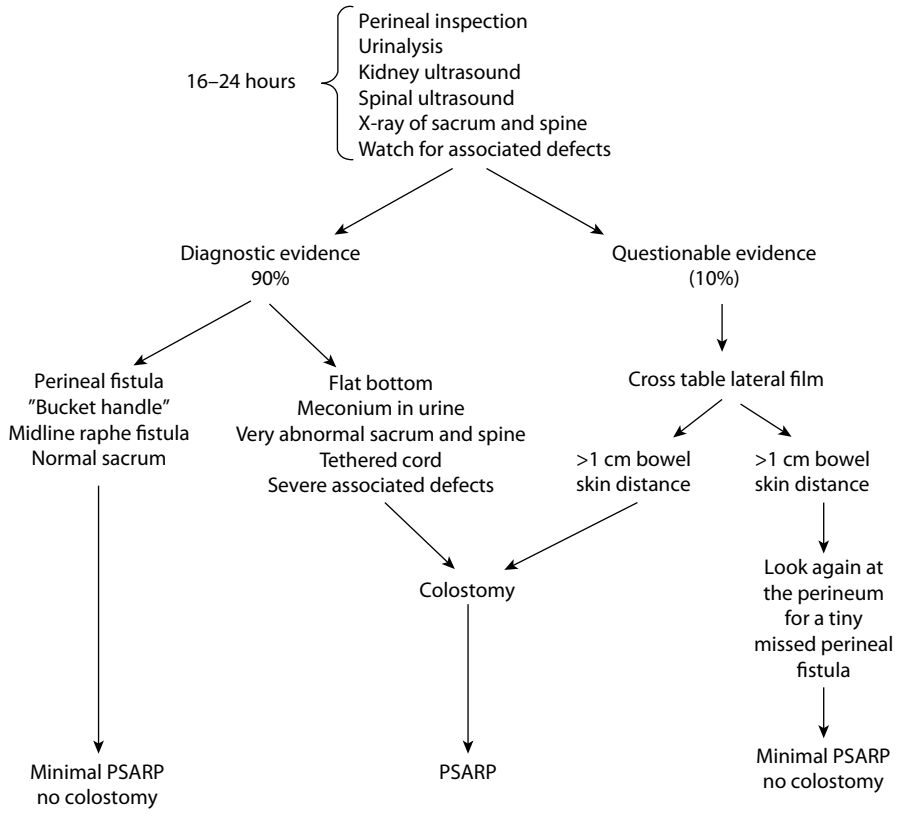

Figure 68.19 Male newborn algorithm for anorectal malformations.

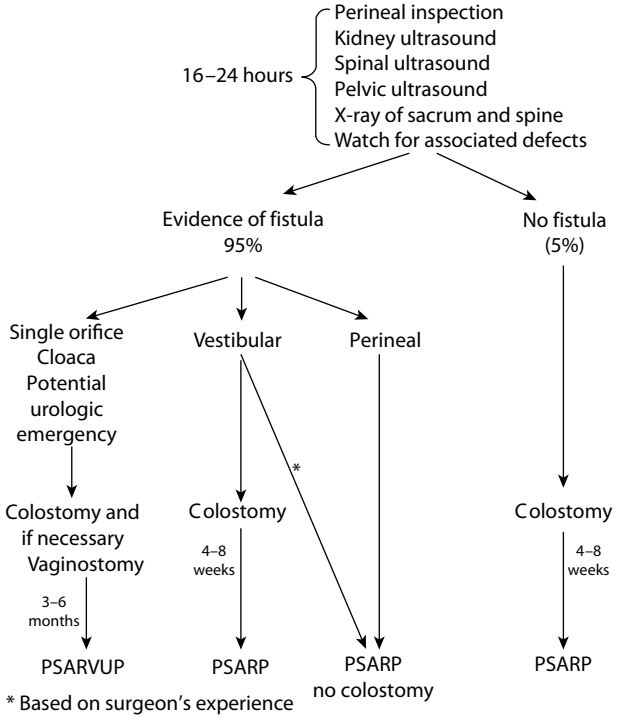

Figure 68.20 Female newborn algorithm for anorectal malformations. PSARP, posterior sagittal anorectoplasty; PSARVUP, posterior sagittal anorectovaginourethroplasty.

coccyx is considered an indication for a colostomy (Figure 68.9). If the patient does not have signs of a rectourinary fistula, most likely, the case is one of imperforate anus with no fistula. If the patient has Down syndrome,[11] it is even more likely. On the other hand, if the rectum is located below the coccyx (Figure 68.8), it means that the surgeon will be able to reach it using a posterior sagittal incision. The surgeon should inspect the perineum again and may find a tiny orifice, so narrow that it did not allow the passage of meconium in the first hours of life. The baby can then be treated with a minimal posterior sagittal anoplasty and without a colostomy.

Figure 68.20 shows the decision-making algorithm used for the initial management of newborn females with anorectal defects. The process of decision making in females is easier than in males, mainly because the vast majority of female patients have some form of fistula either to the perineum, vestibule, or genitalia, which indicates the type of defect that they have.

The presence of a cloaca (single perineal) orifice, as was previously discussed, represents an indication for an urgent urological evaluation. In addition, the patient will require a colostomy and sometimes a vaginostomy. Provided the baby is growing well, the patient may undergo the definitive repair of her defect at age 3–6 months.

In the cases in which the meconium comes from the vestibule, depending on the surgeon's experience, a primary repair or a protective colostomy can be performed. Many times, the

fistula opening is big enough to decompress the bowel, and therefore, there is no need for an emergency colostomy, and the definitive repair can be delayed for several months.

The presence of a cutaneous (perineal) fistula indicates that the baby has the most benign type of anorectal defect. This can be treated with a "minimal" posterior sagittal anoplasty without a protective colostomy. If the perineal fistula is big enough to decompress the intestine, then the anoplasty can be postponed and done on an elective basis. The remaining small group of female patients that have no fistula (5%) need a colostomy followed by a PSARP 4–8 weeks later.

Every surgeon must develop his or her own learning curve in the surgical management of these defects. We like to repair perineal and vestibular fistulae in the newborn period. There are both theoretical and practical advantages in doing these repairs early in life. From the theoretical point of view, placing the rectum in its normal position early may allow the creation of new nerve synapses, which may have advantages in terms of bowel control.[14] From the practical point of view, it is much easier to dilate the anus of a small baby than trying to do it in an older patient. In addition, the babies will not remember the event.

We promote the trend to operate on newborns with anorectal malformations, primarily without a protective colostomy when feasible.[15] In addition, a single procedure is highly attractive when compared to the alternative of three operations (colostomy, main repair, and colostomy closure). However, what remains to be seen is whether or not such treatment will result in better functional results. Those who embrace the new treatment modality (primary repair) are morally obligated to report their results, including complications.

Concerning the laparoscopic approach to these malformations,[16] it must be kept in mind that, as we have described, 90% of the male cases can be repaired via the posterior sagittal route without opening the abdomen; these patients experience minimal pain, eat the same day of surgery, and could even go home the same day of the operation. Laparoscopy was created and conceived as minimally invasive surgery, to avoid the pain and potential complications inflicted by a laparotomy. Actually, there is only one particular defect in males (rectobladder neck fistula), which represents 10% of all malformations in males, that needs a laparotomy to be repaired and therefore, we feel, is ideally suited for a laparoscopic approach. For prostatic fistulas, the approach (laparoscopic or PSARP) should be based on which technique the surgeon feels most skilled at performing. For other malformations such as bulbar urethral fistula, or cases without fistula, we do not think laparoscopy is appropriate. In the female group, we believe that a laparoscopy could be indicated in patients suffering from a very unusual type of cloaca, with a rather short common channel and a rectum located very high in the pelvis; in our series, that malformation occurs only in 4% of the cloacas.

In general, babies with anorectal malformations look healthy unless they have a severe associated defect, mainly urologic, cardiac, or another, serious gastrointestinal tract malformation (esophageal atresia, duodenal atresia). The frequency of associated urologic defects in babies with anorectal malformation varies according to the statistics that one consults.[17–22] In our series, approximately half of the patients with anorectal defects had a significant associated urologic defect, and this frequency varies depending on the level of the fistula site. This, we believe, may help neonatologists and pediatricians to suspect, detect, and treat these defects early.

A constellation of associated findings (single kidney, absent sacrum, esophageal atresia, etc.) can also be detected prenatally.[23] Before the performance of the colostomy, every baby must at least have an abdominal ultrasound done to rule out the presence of obstructive uropathy.

Concerning the passage of meconium, decisions should not be made during the first 16–24 hours of life, since meconium often does not appear, either in the urine or in the perineum, until after that period of time. Abdominal distension does not become a problem during the first 16–24 hours of life. Therefore, decisions as to whether the baby should undergo primary repair or a colostomy should wait for 16–24 hours. It is after that period of time that babies with anorectal malformations will develop abdominal distention; the intraluminal pressure in the rectum will be high enough to overcome the muscle tone of the sphincter mechanism surrounding the most distal portion of the rectum. That is also the reason why diagnostic imaging studies designed to determine the position of the rectum in the pelvis should not be done before 24 hours of life. A collapsed rectum is difficult to see even using the most sophisticated imaging technology.

COLOSTOMY

At birth, once the doctor has made the diagnosis of an anorectal malformation, a nasogastric tube is placed in the stomach and intravenous fluids started. Prophylactic antibiotics are recommended. Twenty-four hours later, the surgeon must decide whether the patient needs a colostomy or a primary procedure to repair the anorectal malformation. We recommend a descending colostomy, with separated stomas: separated enough to allow the placement of a stoma bag over the proximal (functional) stoma, leaving outside the distal stoma, also called mucous fistula—all of this with the specific purpose to avoid the passing of stool from the proximal to the distal colon.

Figure 68.21a shows the type of colostomy that we recommend in the management of anorectal malformations. The advantages of this colostomy[24] over other types include the following:

- Leaves without function only a small portion of the distal intestine, allowing better water absorption.
- It is completely diverting.
- Allows for an adequate length of bowel for the pull-through. One of the most common errors in the opening of a colostomy is leaving a very short piece of distal bowel, which will eventually interfere with the pull-through of the rectum (Figure 68.21b).

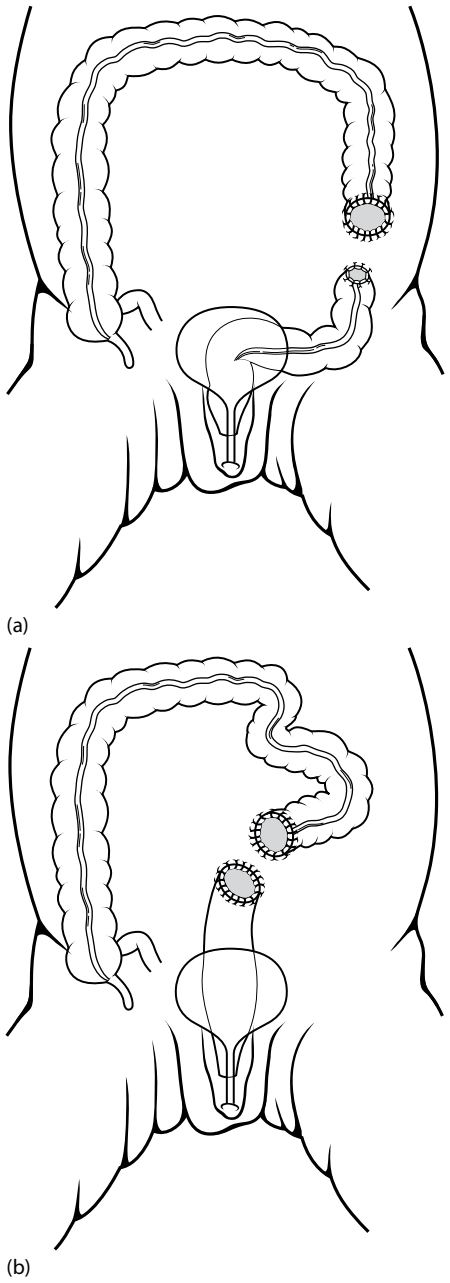

Figure 68.21 **(a)** Ideal colostomy. **(b)** Too-distal colostomy.

- Allows drainage of urine that may pass from the urinary tract back into the rectum.
- Simplifies cleaning of the distal intestine prior to the main repair. It is actually very difficult to clean the distal bowel through a transverse colostomy.
- Makes the distal colostogram easier than when dealing with a more proximal colostomy. It is very difficult to demonstrate the fistula injecting contrast material through a transverse colostomy.
- Reduces the incidence of prolapse.

Loop colostomies are problematic because they allow feces to pass into the distal stoma, provoking fecal impaction, megarectum, and urinary tract infection. Also, there is a risk of contamination and infection of the operative field after the main repair.

Surgical technique for colostomy

The recommended incision measures approximately 6 cm, is made in the left lower quadrant, and is oblique. The proximal functional stoma is placed in the upper and lateral portion of the incision, and the mucous fistula (nonfunctional) distal stoma is intentionally created small and placed in the lower and medial portion of the incision. The distal bowel must be irrigated with saline solution during the operation, in order to remove all the meconium. In this way, the distal bowel remains completely clean and collapsed, and the patient does not need any preparation prior to the main repair.

A colostomy must be considered a serious, delicate procedure. The surgeon must carefully identify the piece of intestine that he or she is going to exteriorize to avoid serious mistakes. The most frequent errors in performing colostomies seen by the authors include the following[25]:

1. A colostomy placed too distal in the sigmoid.
2. Opening of a right upper sigmoidostomy. The surgeon thinks he or she is opening a transverse colostomy and actually grabs the sigmoid colon and exteriorizes it in the right upper quadrant. This interferes with the pull-through.
3. Retracting colostomies. In these cases, the bowel was probably handled poorly and may suffer from ischemia and retraction. In addition, most likely, the bowel was poorly fixed to the abdominal wall. To avoid this, the authors' suggestion is to fix the bowel to the peritoneum and to the anterior fascia.
4. Prolapsed colostomies. Choosing the descending colon to create the proximal, functional stoma avoids prolapse because that portion of the colon is normally attached to the posterior wall of the abdomen. The distal colostomy will never prolapse, even when it is performed in a mobile portion of the colon (sigmoid), because we specifically recommend creating a very small stoma, since it will only be used to irrigate the distal bowel and to perform a distal colostogram.

After the colostomy, once feedings are advanced, the baby can go home. If the baby is growing and developing well, 4–8 weeks later, the main repair can be performed. Prior to the final repair, it is mandatory to perform a distal colostogram in order to determine the precise type of anatomic defect that the patient has. This has important prognostic and therapeutic implications.

Distal colostogram

This is, by far, the most important diagnostic study in dealing with anorectal malformations. The study must be done under fluoroscopy. A Foley catheter is introduced into the distal stoma, the balloon is inflated, and water-soluble

contrast material (never barium) is injected by hand, with a syringe, applying enough hydrostatic pressure to overcome the tone of the funnel-like muscle structure that surrounds the lowest part of the rectum. Failure to observe these principles will most likely show the dye staying above the pubococcygeus line, erroneously indicating the presence of a high defect and not showing the fistula, simply because of lack of hydrostatic pressure.[9] Figures 68.22 through 68.24 show distal colostograms in a case of rectourethral bulbar, rectoprostatic, and rectobladder (bladder neck) fistula. Having this information, the surgeon will be able to plan the surgical procedure. When dealing with a case of rectovesical (bladder neck) fistula, the surgeon will be able to predict that the prognosis in terms of bowel function is not going to be as good as in other types of defects.[5] In addition, the main repair will include a laparotomy or laparoscopy

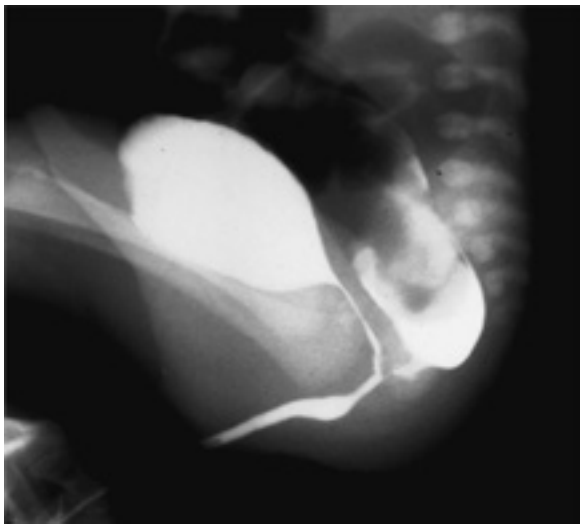

Figure 68.22 Distal colostogram in a rectourethral bulbar fistula.

Figure 68.23 Distal colostogram in a rectourethral prostatic fistula.

Figure 68.24 Distal colostogram in a rectovesical (bladder neck) fistula.

and will take approximately 3–4 hours. Also, a laparotomy or laparoscopy will be necessary in order to mobilize the rectum. Most importantly, the surgeon will avoid looking for the rectum through a posterior sagittal incision where it will not be found, because that would risk injury to the urinary tract, vas deferens, seminal vesicles, and ectopic ureters. The posterior sagittal approach in this case will be used only to show the trajectory of the pull-through, after its mobilization through laparoscopy or via laparotomy, and to allow tacking of the rectum to the muscle complex.

DEFINITIVE REPAIR

Minimal posterior sagittal anoplasty

This operation is done in all defects, traditionally known as low malformations, including perineal fistulas in both male and females. In cases of male newborns, it is important to place a Foley catheter in the bladder during the operation. The purpose of this is to avoid the most common accident seen during these operations, which is the urethral injury. The rectum and urethra are very close together, sharing a common wall. The operation starts by placing multiple sutures and taking the mucocutaneous junction of the fistula. This serves the purpose of exerting uniform traction, which helps in the dissection. The incision is done in the midline and posterior and around the fistula, creating what is also known as a "racket type" of incision (Figure 68.25a). The posterior sphincter mechanism is divided to identify the posterior rectal wall; the dissection then is extended to the lateral walls of the rectum. The most delicate part of the operation is the dissection of the anterior rectal wall. Special attention must be given to avoiding urethral injury. The fistula is mobilized, as well as part of the rectum,

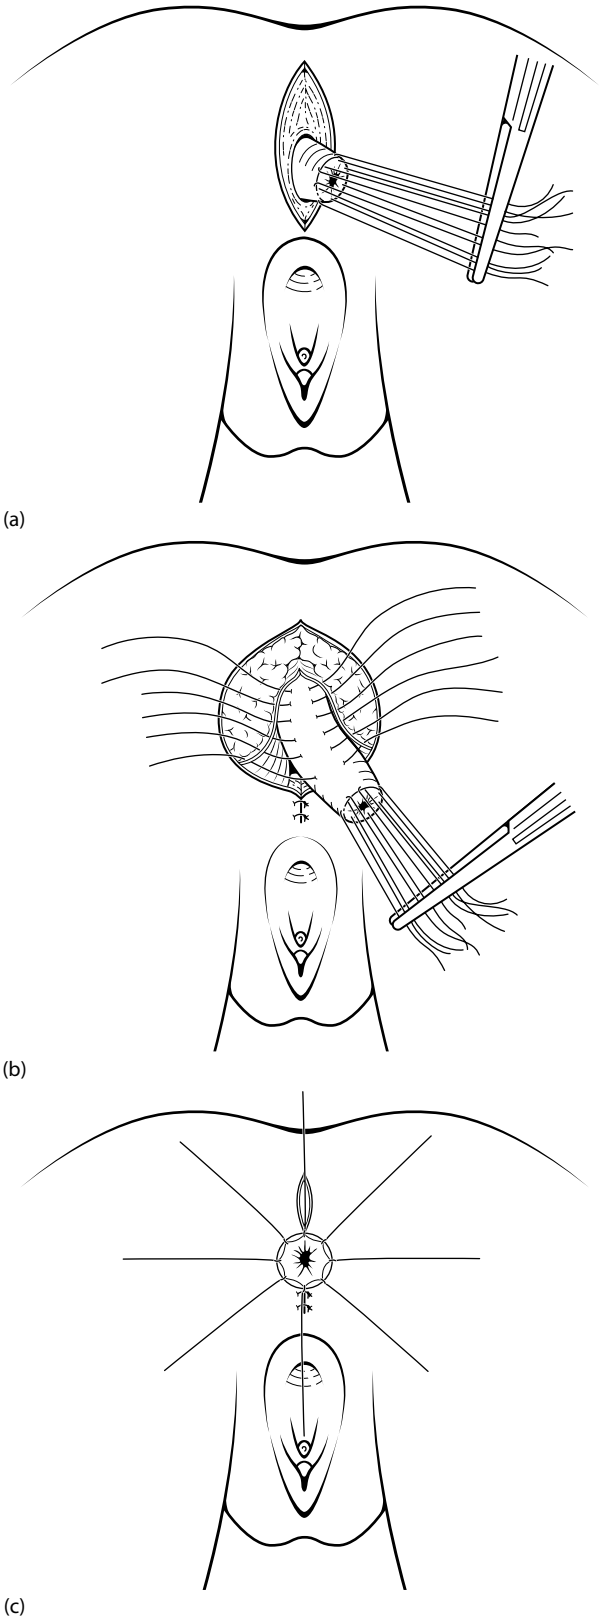

Figure 68.25 Perineal fistula repair: **(a)** incision; **(b)** reconstruction; **(c)** anoplasty.

sufficiently to be posteriorly relocated comfortably within the limits of the sphincter without tension (Figure 68.25b). The rectum is anchored to the muscle complex, and then a 16-stitch anoplasty is done, as shown in (Figure 68.25c).

Limited posterior sagittal anorectoplasty

This procedure is performed in cases of rectovestibular fistula in female newborns. The incision is very similar to the one just described, but it is extended more cephalad as far as necessary to achieve enough bowel mobilization. The main difference with the previous defect is the fact that the rectum and vagina share a rather long common wall. The most important part of the operation consists in separating the rectum and vagina by creating a plane of separation without injuring either one (Figure 68.26). The separation is carried out all the way up, until both structures are completely separated and have a full-thickness normal wall. Lack of adequate rectal mobilization is the main cause of dehiscence after this repair. The separation of the rectum from the vagina requires a meticulous and delicate technique and is performed with a needle-tip cautery, changing from cutting to coagulation where necessary to provide meticulous hemostasis. Once the rectum has been completely separated, the limits of the external sphincter are determined by electrical stimulation. This will indicate where the rectum should be located. The perineal body is then reconstructed with long-term absorbable sutures (Figure 68.27a). The rectum is anchored to the posterior edge of the muscle complex (Figure 68.27b), and then a 16-stitch anoplasty is performed in the same way as previously described (Figure 68.27c,d). If a colostomy is present, these patients can have oral feedings the same day of surgery and can go home the following day. In patients without a colostomy, our routine is to keep them NPO and on intravenous nutrition for 7–10 days. Antibiotic ointment is applied to the wound three times a day for 5 days.

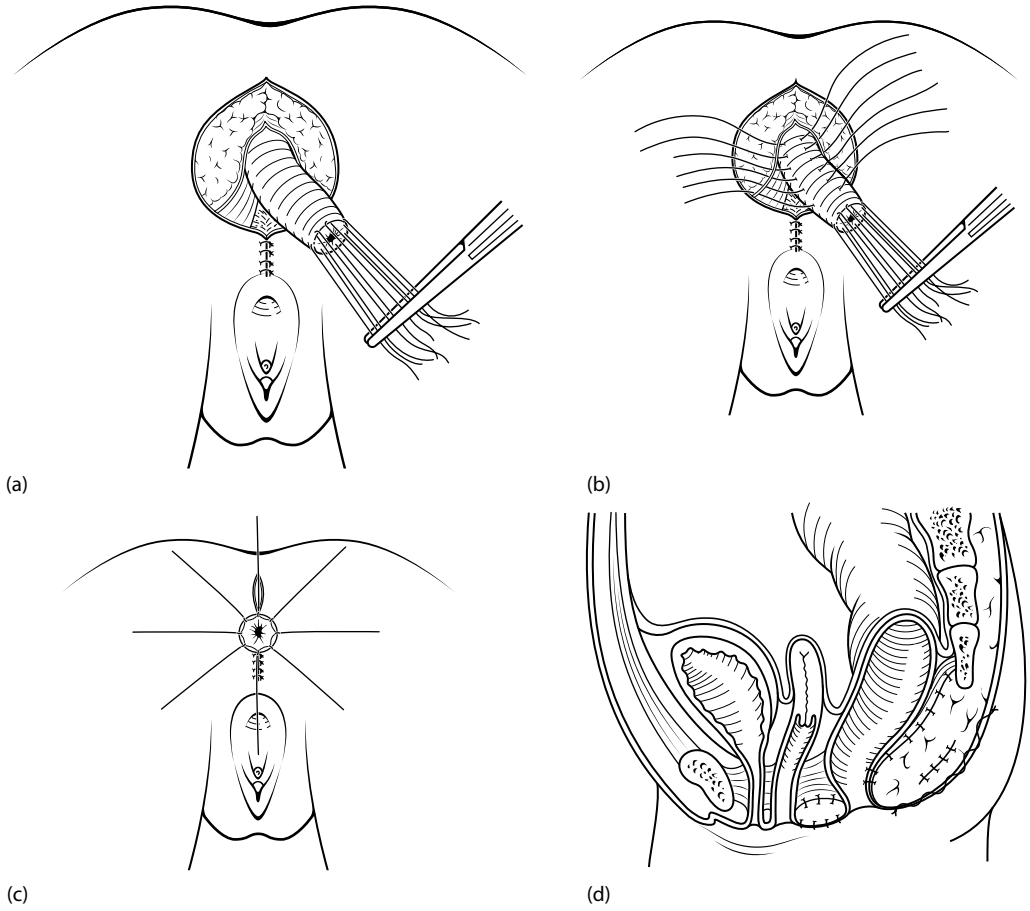

Figure 68.27 Vestibular fistula repair: **(a)** perineal reconstruction; **(b)** anchoring rectum to muscle complex; **(c)** anoplasty; **(d)** operation completed.

Posterior sagittal anorectoplasty

This technique is used for the repair of a rectourethral fistula or a rectovaginal fistula. The patient is placed as previously described in prone position, with the pelvis elevated and with a Foley catheter in the bladder. Electrical stimulation of the perineum will allow the surgeon to identify the anal dimple, which is the location of the center of the sphincter. The incision runs from the lower portion of the sacrum down and through the anal dimple, staying exactly in the midline, leaving equal amounts of sphincter muscle on both sides. After opening of the skin, one can identify the subcutaneous tissue and then the presence of parasagittal muscle fibers. The incision is deepened, and after another area of fat, the ischiorectal space, one finds the levator muscle. The levator muscle continues with the muscle complex down to the skin of the anal dimple, forming a funnel-like structure. Parasagittal fibers that run on both sides of the midline will close the lumen of the anus once this is reconstructed. Muscle complex fibers run perpendicular to the parasagittal ones and also medially. The muscle complex and parasagittal fibers cross perpendicularly, forming the posterior and anterior limits of the new anus (Figure 68.28) Under normal circumstances, in normal individuals, the contraction of the muscle complex and levator occurs simultaneously, elevating and closing the anus. The levator muscle is divided exactly in the midline. The rectum is

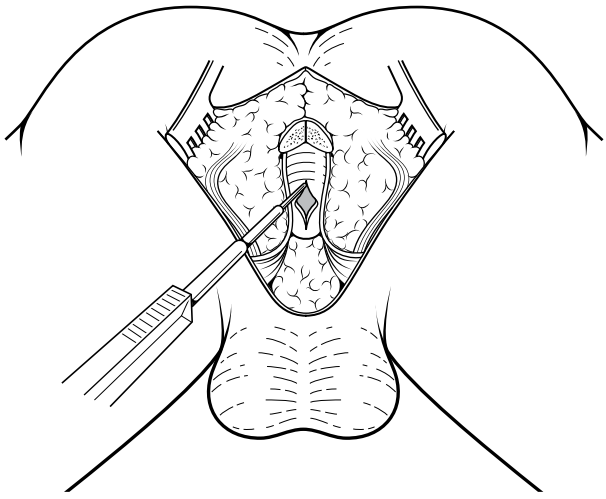

Figure 68.28 Rectourethral fistula repair. Anatomy exposed. Parasagittal fibers, muscle complex, and levator muscle have been split in the midline. The rectum is open in the midline.

then opened along its posterior wall between two traction sutures. Once the rectum is opened, one can visualize the fistula site. One must remember that the rectum and urethra share a common wall immediately above the fistula. Accordingly, a submucosal dissection must be carried out above the fistula site (Figure 68.29). After approximately 1 cm of submucosal dissection, the dissection continues taking the full thickness of rectal wall. Once the rectum has been separated from the urethra, the fistula is closed with interrupted long-term absorbable sutures. The rectum is then dissected in a circumferential manner, in order to gain enough length to reach the perineum without tension (Figure 68.30).

Tapering as shown in Figure 68.31 is rarely needed but, if necessary, must be carried out in the posterior aspect of the rectum. The bowel must then be closed in two layers of interrupted sutures. The rectum is then placed in front of the levator muscle within the limits of the sphincter mechanism and is also anchored to the posterior edge of the muscle

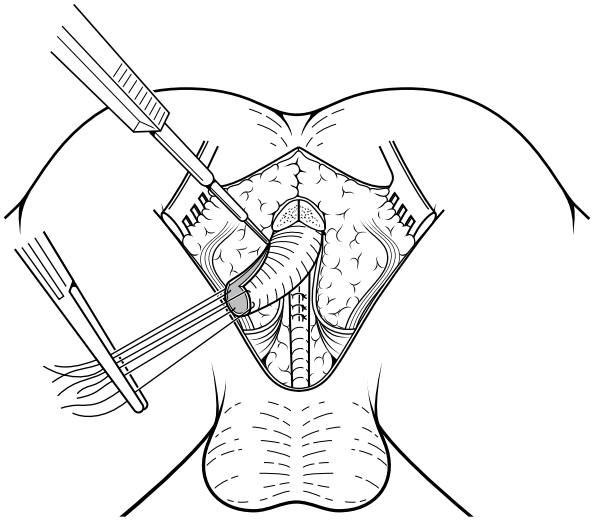

Figure 68.31 Tapering the rectum (when necessary).

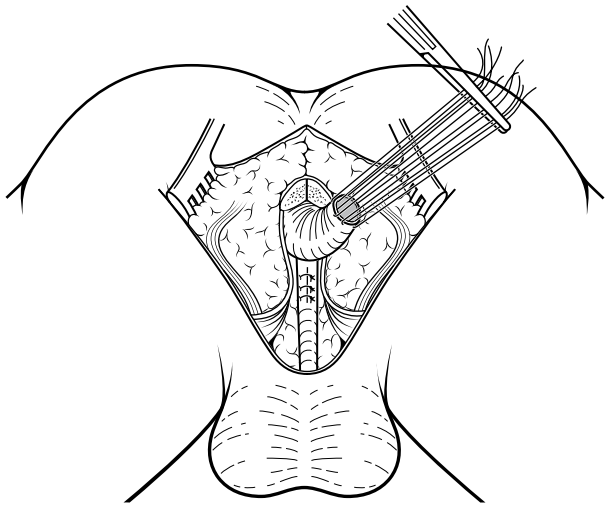

Figure 68.30 Rectum separated from urethra.

complex to prevent prolapse (Figure 68.32). The anoplasty is done as previously described (Figures 68.33 and 68.34).

Following the operation, the Foley catheter must remain in place for 7 days. If the catheter comes out accidentally, it is better to leave it out rather than trying to pass it back into the bladder and thus risking a urethral perforation at the urethral suture site. Most of the time, babies will be able to void with no difficulty. If this is not so, which luckily is rare, then a suprapubic cystostomy is recommended.

Posterior sagittal anorectoplasty and laparoscopy or laparotomy (bladder neck fistula)

This technique is used in cases with a very high defect, known as recto–bladder neck fistula in males. Some surgeons with experience in laparoscopy can also repair rectoprostatic fistulas with laparoscopy.

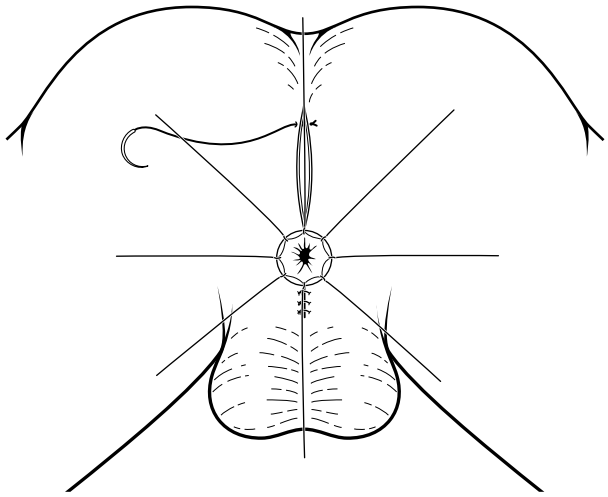

Figure 68.33 Anoplasty.

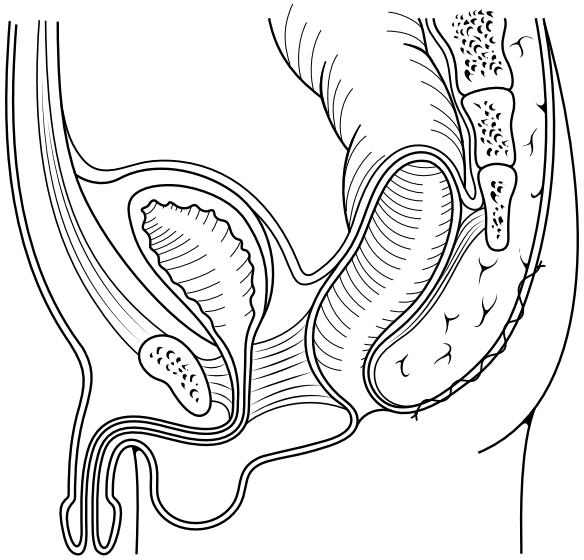

Figure 68.34 Anoplasty—operation completed.

The operation is started with the patient in the supine position. The baby is prepared with a total body preparation from nipples down. A Foley catheter is placed in the bladder. The abdomen is entered with laparoscopy, the peritoneal reflection is opened, and the sigmoid colon is dissected down to the fistula site where it is ligated and divided. The rectum in these cases opens into the bladder neck in a "T" fashion with no common wall, and therefore, the separation from the bladder is relatively easy. One must be careful to avoid damage to the vas deferens, which runs very close by. The perineal incision is the same as previously described for the posterior sagittal anoplasty but can be done in supine position with the patient's legs elevated. The sphincter mechanism is divided in the midline, and the presacral space is identified. Getting a high rectum to reach the perineum may be challenging and requires a meticulous dissection along the rectal wall, which is dependent on the rectum's excellent intramural blood supply. A colostomy placed too distal in the sigmoid may interfere with the rectal mobilization. Also, if the distal rectum requires tapering, this may need to be done with an open abdomen. Once mobilized, the rectum is pulled through, down to the perineum. The rectum is tacked to the posterior edge of the muscle complex, and the anoplasty is done as previously described. The Foley catheter remains in the bladder for 7 days.

The posterior sagittal approach has also been used since 1982 to repair cloacas.[13] Since cloacas represent a spectrum, the operations to repair these defects may last from 3 to 14 hours and should be carried out by surgeons with significant experience. The technical maneuver that is called total urogenital mobilization has greatly facilitated the repair.[26] Using total urogenital mobilization, the rectum is separated from the vagina, and then both the urethra and vagina are mobilized together, down to the perineum. This maneuver also avoids the formation of urethrovaginal fistulas as well as vaginal stenosis. The more complex cases with common channels of 3 cm or greater require a variety of surgical maneuvers including specialized vaginal mobilizations or replacements to complete the repair.[13]

Two weeks postoperatively

After 2 weeks, the anus is calibrated, and the parents are taught to dilate, which they do twice a day, going up in size each week until the desired size is reached, at which point the colostomy can be closed. Dilations are continued thereafter with a tapering protocol.

Once the desired-size dilator goes in easily, with no pain (twice a day), the parents may start tapering the frequency of the dilatation:

- Once a day for a month
- Every other day for a month
- Every third day for a month
- Twice a week for a month
- Once a week for a month
- Once a month for 3 months

The ideal sizes of Hegar dilators are as follows:

- Number 12 for 1–4 months old
- Number 13 for 4–8 months
- Number 14 for 8–12 months old
- Number 15 for 1–3 years old
- Number 16 for 3–12 years old

Results

Each defect described here has a different prognosis. The patients with lower defects usually have excellent results, except when technical errors have been made or if they have associated sacral or spinal problems.

Table 68.2 shows the results obtained in our series. The patients with a sacral ratio (Figure 68.35) of less than 0.3

and flat perineums have fecal incontinence regardless of the type of malformation or quality of the repair. Normal sacral ratios (>.07) usually correlate with good functional prognosis.

Because persistent cloacas themselves represents another spectrum of defects, they will vary as far as potential for bowel and urinary control. The length of the common channel seems to be the most important prognostic factor for urinary control. Bowel continence seems to be influenced more by the quality of the sacrum.

BOWEL MANAGEMENT FOR FECAL INCONTINENCE

For patients suffering from fecal incontinence as a sequela of their anorectal malformations (25% of patients), we implement a bowel management program that is used after the child reaches 3 years of age.[27] The goal is to send these children to school in normal underwear. The program is implemented by trial and error, over a period of 1 week. It consists of teaching the family to clean the patient's colon once a day with an enema tailored to work for the specific child. This implementation is radiologically monitored every day during that week until the specific type of enema capable of cleaning the colon is found and the patient's underwear is kept completely clean for 24 hours.[28,29] Every year, during vacation time, the patient is subjected to a laxative test; the enemas are stopped, and the capacity of the patient to become toilet-trained without enemas is evaluated. If the patient is not ready, he or she goes back to the enema program. When the patients are old enough, sometimes they express dissatisfaction with rectal enemas; they want more privacy and do not want their parents giving them enemas. In order to further improve their quality of life, the family

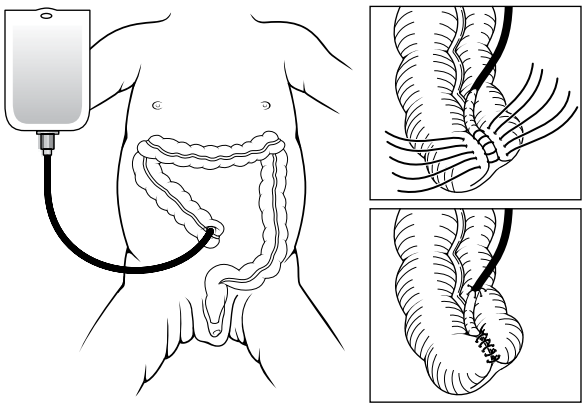

Figure 68.36 Malone appendicostomy.

is offered a procedure called *continent appendicostomy* (Malone procedure) (Figure 68.36).[30,31]

Congenital pouch colon

AMULYA K. SAXENA AND PRAVEEN MATHUR

INTRODUCTION

Congenital pouch colon (CPC) is a malformation of the colon in which the entire large bowel or segments of varying lengths of the large bowel exhibit enormous dilatations in the form of a pouch and communicate with a distal fistula to the urogenital system. CPC is a condition that comprises a high form of anorectal malformation associated with large variations in the size of the dilatations of the affected colonic segment. The scarce reporting of this condition in the 1980s precluded its inclusion in the Wingspread classification of anorectal malformations; however, with the increasing number of reports and detailed investigations of the condition, CPC has been recognized as a rare form of anorectal malformation and has been included in the Krickenbeck classification.[1]

HISTORICAL INSIGHTS

CPC is a rare congenital malformation that is almost nonexistent outside the Indian subcontinent. However, this anomaly was initially recognized in England during the beginning of the twentieth century. The first description of this anomaly was documented by Spriggs[2] from a specimen carefully observed at the London Hospital Museum in 1912. He described the specimen as having an absence of half of the large bowel and rectum, where the dilatation was presumed to be the result of a congenital occlusion of the gastrointestinal tract. The next reporting of this congenital malformation was published almost half a century later in an article from Canada in 1959. In this publication, a more accurate account was provided by Trusler et al.,[3] who described more typical characteristics of this malformation, such as the pouch-like dilatation of the shortened large bowel and its association with a high form of anorectal malformation. In 1967, El-Shafie[4] described this malformation in detail as a congenital shortening of the small intestines that accompanied a cystic dilatation of the colon associated with an ectopic anus.

CPC was first reported in India in 1972, when Singh and Pathak[5] coined the term "short colon" after observing this condition in a series of six patients. The authors also speculated in this report on the possible embryogenesis of the malformation. Later on, in a successive report in 1977, a description of the anatomy of this malformation was published.[6] An important contribution to CPC was made by Chiba et al.[7] in 1976, who not only made the first attempts to classify this malformation but also reported on the management of this malformation with the technique of "coloplasty." The term "colonic reservoir" was coined by Gopal[8] in 1978 in a report with this malformation with the distal end of the reservoir terminating into the female genitals through a rectovaginal fistula. Further efforts to describe this malformation as a "short colon malformation" associated with an atresia of the anus were made by Li in 1981.[9]

Narasimha et al.[10] in 1984 proposed the term *pouch colon syndrome* for this malformation and, after observing variations in the presentation of this malformation, presented a classification based on the length of normal colon preceding the pouch dilatation. Cloutier et al.[11] in 1987 described this malformation as a "rectal ectasia" in a newborn with a low anorectal malformation and reported an incidence of 5% of terminal bowel ectasia in their patients with low anorectal deformities. Wu et al.[12] in 1991 suggested elaborate terms to describe this malformation with acronyms such as "association of imperforate anus with short colon" (AIASC) or "association of imperforate anus with exstrophia splanchnica" (AIAES). However, Chadha et al.[13] in 1994 coined the term "congenital pouch colon," which is the nomenclature to aptly describe this anomaly.

INCIDENCE

The largest patient series of CPC are being reported exclusively from India. Smaller series of patients are being reported from neighboring countries in the Indian subcontinent such as Pakistan and Nepal but with a low incidence reported from Bangladesh.[14] Sporadic cases of CPC

are being reported from the Middle East, Far East, Europe, and North America.[15–18] The incidence of CPC is the highest in the northwest regions of India and is estimated to be 5%–18% of the total number of neonates managed for anorectal malformations. Among the Indian Tertiary Care Centers reporting on large series of CPC, Udaipur in the western State of Rajasthan has reported the highest incidence of CPC in India, accounting for 37% of the high forms of anorectal malformations (which is more than double that reported in Delhi—5.2%).[19]

CPC more frequently affects the male population, with a male–female distribution of 4:1. The sex ratios of CPC reported in case reports or small series outside India predict equal gender distribution, which are not accurate since the sample size is too small to derive valid conclusions.

ETIOLOGY

The embryogenesis of CPC is not known, and the etiology is still quite elusive. The widespread use of and direct contact with pesticides in agriculture-based communities have been regarded as the possible factor in triggering of events that lead to CPC. It is also important that the effect of these factors influences the fetus after conception at a time when the hindgut is differentiating into the urinary and colonic tracts.

Various theories have been hypothesized to explain the formation of the pouch. The *chronic obstruction theory* proposed that the expansion of the large bowel was a result of chronic obstruction of the distal colon.[3] However, this theory has not been accepted since the dilated pouch does not return to assume normal proportions even after a colostomy placement to relieve the obstruction. Another hypothesis is the *interference of hindgut growth and migration theory* proposed by Dickinson.[20] In this hypothesis, it was proposed that the interference in the longitudinal growth of the hindgut (distal to the *allantois*) and failure of its migration into the pelvis following the obliteration of the inferior mesenteric artery in early embryonic life was responsible for the formation of the short colon. The *altered hindgut stimulation theory* was hypothesized by Chatterjee.[21] This theory proposed that the normal development of the cecum and the right colon was stimulated by the normal developing hindgut, and development alterations in the hindgut resulting from a primary disorder were responsible for the altered development of the cecum or the right colon. The *faulty rotation and fixation theory* proposed by Wu et al.[12] hypothesized that the faulty rotation and fixation of the large bowel was responsible for the disturbances in longitudinal growth. The *vascular insult theory* was proposed by Chadha et al.[13] in which degrees of vascular insult at the time of the partitioning of the cloaca by the urogenital septum were deemed responsible for the malformation and could explain its variations. The *vascular insult theory* was also supported by Mathur et al.[19] in explanation of double pouch formation in CPC. At present, vascular insults best explain the formation of CPC, which is evident by the abnormal vascular supply to the pouch. Also, the overwhelming vascular support provided by the superior mesenteric artery to the entire distal bowel supports this view, since the inferior mesenteric artery has been identified only in few patients with CPC during surgery.

PATHOLOGY

CPC is recognized by certain pathological characteristics that are solely found to be associated with this congenital malformation (Figure 69.1).

Gross pathology

1. The presence of anorectal malformations, which differentiates this entity from segmental dilatation of the colon.
2. Irrespective of the CPC type, there is a decrease in the length of the large bowel due to the presence of the pouch.
3. The pouch formations may differ in length and diameter and are feces or meconium impacted at the time of surgery.
4. The pouch wall is thick with a stiff consistency and is abruptly connected to the normal bowel without the presence of the transition zone.
5. There is an absence of haustrations, teniae, and appendices epiploicae in the pouch colon.
6. An abnormal vascular supply to the pouch can always be identified during surgical exploration.
7. A fistula can be identified to the urinary tract in male neonates (colovesical fistula) and to the genitourinary tract in females (colocloacal, colovaginal, or colovestibular fistula).
8. Appendiceal anomalies are present and vary from complete absence to the presence of double appendices.

Histological pathology

Histological studies of resected pouch colon demonstrate extreme variations in CPC. In most patients, acute and

Figure 69.1 Operative view of the exteriorized grossly dilated congenital pouch colon segment visualized from a left lower quadrant "hockey-stick" incision.

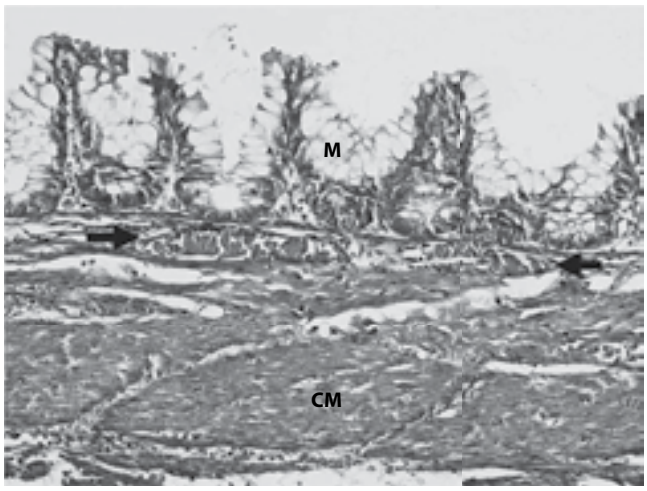

Figure 69.2 General features in the histopathology of pouch colon include inflammation of the mucosa (M) and disorganized colonic wall musculature (CM). Submucosal hemorrhage (arrows) is evident in this specimen. (Stain: Massom trichome, 20× magnification.)

chronic inflammation of the mucosal and submucosal layers is present with varying degrees of hemorrhage along with the presence of disorganized muscle layers in the colon wall (Figure 69.2). Hypotrophy of the muscle layers has been observed, which is more predominant in the outer muscle layer of the pouch.[22] Extreme variations in the muscle layer (both circular and longitudinal) have also been found, which include fibrosis, atrophy, and hypertrophy along with muscle disruption.[23] Investigations have also shown variations, from the presence of normal colon wall with normal ganglion cells in some patients to a poorly developed colon wall musculature with decreased or absent ganglion cells in others.[6,10,13,24] Interestingly, heterotrophic tissue such as gastric mucosa, small intestinal mucosa with characteristic villi, and pancreatic tissue has also been found in pouch specimens of CPC patients.[10,22]

CLASSIFICATION

CPC can present in various types, and efforts have been made to classify CPC in order to provide a basis for surgical management as well as for evaluating the outcomes.

The first efforts to classify CPC were made using a *classification based on characteristics of short colon* that grouped pouch colon into five types.[7] However, many features described in this classification did not associate with the CPC pathology. CPC was then classified by a *classification based on presence of normal colon length proximal to the pouch* into four types.[10] Although this classification had identified the major forms of CPC, it had major drawbacks since the length of the normal colon was determined using terms such as "short segment" and "significant length," and appropriate parameters or anatomic landmarks to determine the normal colon length were absent. A further classification was proposed, a *classification based on coloplasty*, which divided CPC into two types.[24] This classification was further modified into a *classification based on pull-through*, which also broadly divided CPC into two types.[25] The last two classifications considered the surgical approach with regard to coloplasty or pull-through; however, both of them offered no information about the length of the normal colon in CPC patients.

The Saxena–Mathur classification for CPC is a *classification based on anatomic morphology* and divides CPC into five types (Figure 69.3)[26]:

- *Type 1 CPC*—normal colon absent and ileum opens into pouch colon
- *Type 2 CPC*—Ileum opens into a normal cecum, which opens into pouch colon

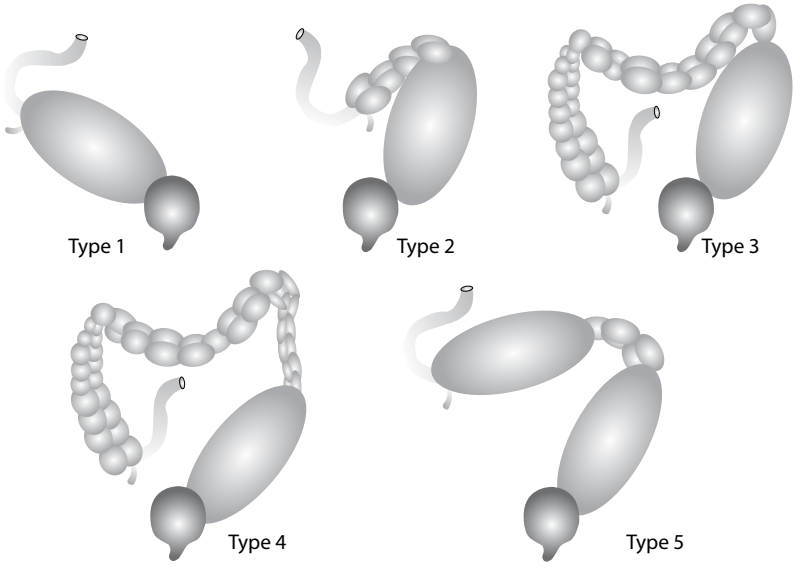

Figure 69.3 Distribution of patients into five types of congenital pouch colon according to the Saxena–Mathur classification.

- *Type 3 CPC*—normal ascending colon and transverse colon open into pouch colon
- *Type 4 CPC*—normal colon with rectosigmoid pouch
- *Type 5 CPC*—double pouch colon with short normal interpositioned colon segment

This classification employs anatomic landmarks to determine the length of the normal colon as well as identifies the relation of the pouch to the normal colon. It also includes rare forms of CPC such as double pouch colon and offers clear guidelines toward management of CPC.

HISTORY AND PHYSICAL EXAMINATION

The presence of an anorectal malformation with gross distention of the abdomen is the hallmark of the physical examination. In male neonates, discharge of meconium (meconurea) or stool through the urethra via the colovesical fistula is evident, and these neonates are generally referred for treatment in the immediate neonatal period. However, in female patients, meconium and fecal discharge through a cloacal, uterine or vaginal fistula may delay referral in a stable neonate. Furthermore, when a colocloacal fistula (common in females with CPC) is present, it is associated with a large fistula opening that permits decompression of the pouch colon contents, the presence of which can further delay presentation in female subject for a period of several months after birth. At the time of referral, these patients with colocloacal fistulas are frequently obstipated, and physical examination shows the discharge of stools from the ectopic site.

PRESENTATION

The majority of patients with CPC present in the immediate neonatal period due to the anorectal malformation. The absence of the anal canal and excessive distention of the abdominal cavity are the two characteristic signs that raise suspicion of CPC. Although in CPC, the pouch ends through a fistula in the genitourinary tract, meconurea may be present or absent. Another common symptom in these neonates is serial episodes of bilious vomiting, which is a major symptom that leads to referrals. Delayed referrals or grossly distended pouch colon is associated with colonic perforations, which present a major challenge in the management of the newborn with septicemia and peritonitis, which further worsens the respiratory distress present due to the massive abdominal distension. Delay in diagnosis and late referrals even in the neonatal period have been largely responsible for the high mortality in CPC. Awareness of the condition and development of proper management strategies, especially through improvement in neonatal intensive care at the tertiary centers in India, have drastically reduced the mortality from 40% to the present rate of 15%.[27]

DIAGNOSIS

Plain erect abdominal radiographs performed to diagnose patients with CPC demonstrate a classical solitary, grossly dilated air fluid bowel loop that occupies more than 75% of the abdominal cavity with displacement of the small intestines (Figure 69.4). The position of the pouch and the displacement of the intestinal loops depend on CPC type.[24] Although plain abdominal radiographs can predict the CPC type, the definitive diagnosis and the CPC type can be determined only after surgical exploration.[28] False diagnosis of CPC based on plain radiographs is possible in (1) patients with significant dilatation of the sigmoid colon, (2) patients with pneumoperitonuem after perforation in anorectal malformations due to late presentation, and (3) female neonates with rectouterine fistula when severe dilatation of the meconium-filled uterus and gas exhibit the classical images of CPC radiographs.[29]

Although plain erect abdominal radiographs with the classical presentation of CPC are sufficient to establish the diagnosis, conventional invertograms used for the diagnosis in anorectal malformations are additionally performed. Prior to surgical management, further investigations such as abdominal ultrasonography, intravenous pyelography, or voiding cystouretherography and echocardiography are mandatory since a wide range of genitourinary, gastrointestinal, and other forms of associated anomalies have been found in patients with CPC (Table 69.1).

Figure 69.4 Plain abdominal erect radiograph demonstrating the classic grossly dilated pouch colon segment occupying a large area in the left abdomen, thereby displacing the small intestines toward the right abdomen.

Table 69.1 List of associated anomalies reported in congenital pouch colon patients

Genitourinary anomalies	Gastrointestinal anomalies	Other organ anomalies
Hydronephrosis	Absent appendix	Sacral agenesis
Vesicoureteral reflux	Double appendix	Congenital heart disease
Bicornuate uterus	Malrotation	Myelomeningocele
Cryptorchidism	Colon duplication	Prune belly syndrome
Hydroureteronephrosis	Meckel diverticulum	Hemivertebrae
Hypospadias	Double Meckel diverticulum	Congenital talipes equinovarus
Renal aplasia/agenesis	Esophageal atresia	Perineal teratoma
Renal dysplasia	Small intestinal duplication	Absent ribs
Double uterus	Rectal atresia	Down syndrome
Double vagina		
Septate vagina		
Ectopic kidney		
Urethra duplication (males)		
Urethral diverticula		
Bifid penis		
Megalourethra		
Urethral strictures		
Bladder exstrophy		
Duplicate bladder exstrophy		

Note: List of associated anomalies in congenital pouch colon patients distributed under genitourinary, gastrointestinal, and other organ manifestation categories.

MANAGEMENT

Preoperative management

The preoperative management is broadly dependent on the condition of the pouch (intact versus perforated). In stable neonates, preoperative management includes gastric decompression using a wide-bore nasogastric tube, intravenous fluid replacement to correct the effects of dehydration and electrolyte imbalance, and placement of a urinary bladder catheter. Antibiotic therapy is commenced and extended depending on the state of the inflammation in the pouch colon evaluated during the surgery. In neonates presenting with pouch perforations along with signs of either peritonitis or septicemia, aggressive intensive care management is necessary to stabilize the neonate for the emergency surgical procedure, which is limited to evacuation of the meconium or stool from the peritoneal cavity, placement of a ileostomy or colostomy, and closure of the perforation site. The intention in surgical management in neonates with perforations is to perform the surgery with the smallest possible incision and to complete the procedure in a short time.

Operative management

The Management algorithm of CPC is based on the type of pouch according to the Saxena–Mathur classification (Figure 69.5).[30] An abdominal incision in the lower left quadrant in shape of a hockey stick has been found to offer optimal access to inspect the malformation with the primary intention of fistula ligation irrespective of the CPC type. After the fistula has been exposed and ligated, the condition of the pouch dictates the further operative strategy. Staged procedures, employing the placement of a protective ileostomy or colostomy with ligation of the fistula in the first stage, followed by an abdominoperineal pull-through in the second stage, still offer the safest option when compared to one-stage surgery, which is associated with a higher incidence of morbidity and even mortality. The intention of surgical management in CPC is to evaluate the amount of large bowel affected and to salvage its maximum length in order to restore or partially restitute the functions of the large bowel such as absorption, transportation, and containment.

In Type 1 and Type 2 CPC, a one-stage procedure (pouch excision and pull-through) or three-stage procedure (ileostomy, pouch coloplasty with pull-through, and ileostomy closure), depending on the condition of the pouch (ischemic or healthy), can be performed. In case of severe ischemia and perforations, resection of the pouch remains the only alternative. If the pouch is resected, either a direct pull-though of the ileum or placing a protective ileostomy with delayed ileum pull-through offers the best surgical option. However, if the pouch is healthy, the surgical approach is focused on attempts to rescue and taper the pouch and to perform a pouch coloplasty through pouch tubularization. Pouch tubularization is performed after pouch mobilization and longitudinal incision on the antimesenteric side (to preserve the vascular supply) with edge reapproximation over a catheter. Although tubularized pouch coloplasty is performed in both Type 1 and Type 2 CPC, it is not uncommonly associated with increased morbidity in terms of incontinence and complications resulting from

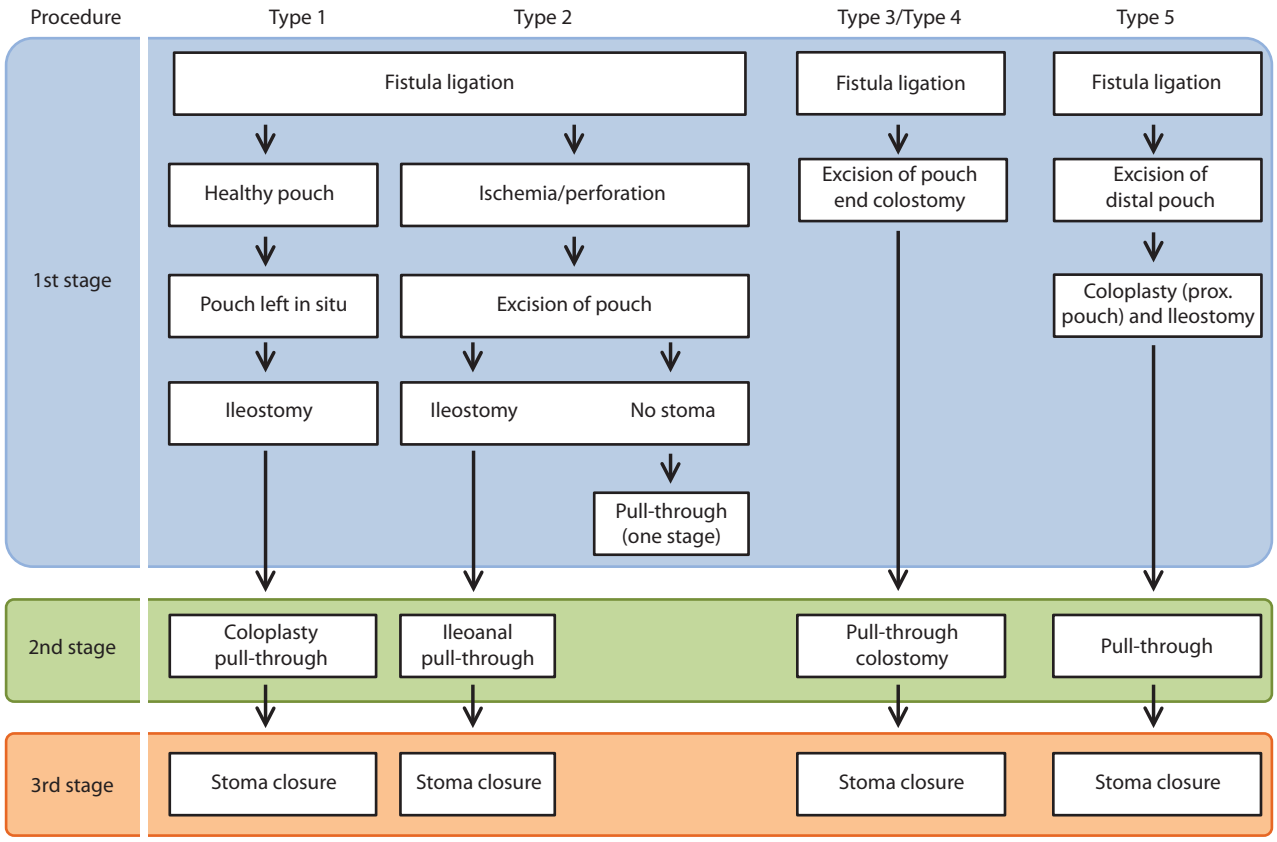

Figure 69.5 Management overview of the various types of congenital pouch colon with outline of the operative stages.

redilatation of the tubularized pouch.[31,32] Also, variations in the outcomes of surgery have been reported by various centers.[12,31,33,34] The function or the absorptive capability of the tubularized pouches is not understood; however, it is reported to be decreased since attempts to patch or augment healthy pouch colon onto normal pull-through ileum in Type 1 CPC with the intention of rescuing the absorptive surface area have been reported with success.[35]

With regard to redilatations of tubularized pouches, the technique of "window" colostomy needs to be addressed. This technique involves the placement of a stoma directly on the pouch colon, which is the most prominent part of the dilated bowel, in an attempt to provide primary decompression in a sick neonate, when extensive surgical exploration is not possible. Window colostomies are more frequently performed by surgeons not well acquainted with this malformation and are commonly associated with urinary complications when the fistula is left open. Furthermore, enormous prolapse of the pouch and failure to thrive also have been related to the placement of window colsostomies.[36] Window colostomy is also associated with mortality in patients who have been managed with this option. The option of window colostomy should not be considered in a stable infant.

The significance of the Saxena–Mathur classification in differentiating Type 1 and Type 2 CPC is to recognize the presence of the normal cecum in Type 2 CPC, which is underestimated in the classifications based on surgical approach. Various investigations and experimental studies have demonstrated the significance of the cecum and ascending colon or parts of the ascending colon in the absorption of sodium, which influences the exchange of chloride and bicarbonate in these tissues.[37,38] However, investigations need to be performed to validate these differences in patients and compare Type 1 and Type 2 CPC patients. Similarly, the absorption of potassium, which is significant in the descending colon in experimental studies,[39,40] highlights the difference between the Type 3 and Type 4 CPC since the normal functioning descending colon is only present in Type 4 CPC.

The presence of considerable lengths of normal colon in the Type 3 and Type 4 CPC enables total resection of the pouch and a staged abdominoperineal pull-through of normal colon (Figure 69.6). The approach to Type 3 and Type 4 involves the ligation of the fistula, excision of the pouch, and placement of a stoma, which is followed by a delayed abdominoperineal pull-through. Although it is debatable if a protective colostomy should be placed, or a prior high colostomy be closed during the pull-through procedure, the authors prefer the first option and place a protective colostomy during the pull-through, which is returned at a later point of time. In Type 3 and Type 4 CPC, if the high colostomy is chosen (instead of the end colostomy), appropriate placement of the colostomy is advocated since improper placement of a high colostomy may

Figure 69.6 Operative view of a Type 3 CPC demonstrating the transition of normal transverse colon (left) to the pouch dilatation (right).

interfere with the pull-through procedure, especially if the length of the colon to be pulled through is too short.

Management of Type 5 CPC requires the approach of two pouch colon segments that are separated by a segment of normal colon and is best done by a three-stage procedure (Figure 69.7).[19] The first procedure involves the ligation of the fistula, excision of the distal pouch, tubularization of the proximal pouch, and the placement of a protective ileostomy. The second procedure involves the abdominoperineal pull-through keeping the protective ileostomy. In the third procedure, the protective ileostomy is returned. Another option for Type 5 CPC would be to tubularize both the proximal and the distal pouch.

Surgical management of female neonates with pouch colon is complex due to the frequent association with the cloaca as well as the associated anomalies of the genital system.[41,42] Depending on the complexity of the genital anomalies, a one-stage or three-stage approach is preferred; however, there is no consensus on the approach to date. The pouch colon has been tubularized to create a neovagina and reconstruct the anorectum with preserved vasculature also using the longitudinal incision technique.[16]

Postoperative management

The postoperative management depends on the condition of the pouch. In patients with pouch perforation, intensive care support along with parenteral nutrition is necessary until complete recovery. The use of antibiotics and the duration of treatment are also dependent on the surgical findings. In patients with protective colostomy, feeds are commenced earlier than in those who have undergone tubularization and pull-through procedures. Monitoring of bowel movements is necessary to achieve success in these patients.[43] Regular postoperative follow-up is necessary to document the bowel movements, which could range from diarrhea when the pouch is resected to obstipation, which could result in tubularized pouch redilatation and necessitate further surgical procedures.

COMPLICATIONS

Complications in the management of CPC can be divided into five distinct categories, which are related to (1) window colostomy, (2) protective colostomy, (3) tubularized pouch colon, (4) complete pouch resection, and (5) pull-through procedure. Window colostomy leads to a wide range of complications such as incomplete pouch decompression, prolapse, stoma recession, stoma stenosis, pouchitis, enterocolitis, and failure to thrive. The complications of protective colostomy or pull-through procedures are general complications associated with these procedures and are not specific to CPC. Tubularization of the pouch colon could be associated with complications of leakage along the suture line with consequent rupture. Also, redilatation after tubularized colon has been observed after long-term follow up

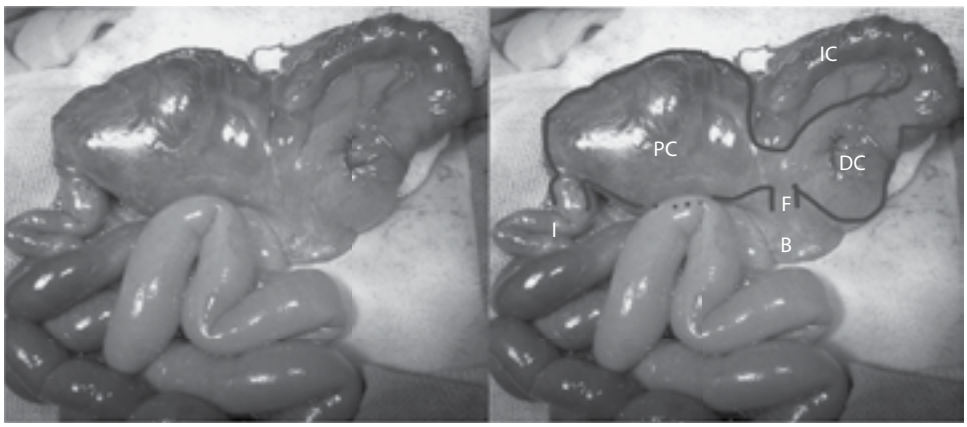

Figure 69.7 Operative view of a Type 5 CPC demonstrating the double pouch colon. (B, urinary bladder; DC, distal pouch colon; F, fistula; I, intestine; IC, intermediate colon; PC, proximal pouch colon.)

in patients with salvaged pouch colon.[32,44] Complete pouch resection is associated with the complications of recurrent watery diarrhea; excoriation around the anus, perineum, or genitals; and poor weight gain. Severe complications in neonates with pouch perforations not only are limited to the septicemia and peritonitis but also have been found to negatively influence the respiratory status as well as the anesthesia efforts intraoperatively and postoperatively, with lethal outcomes.[45]

OUTCOMES

CPC is a complex form of high anorectal malformation, and the muscle complex responsible for maintenance of continence directly influences the long-term outcomes in these patients. In types of CPC where sufficient normal bowel is present (Type 3 and Type 4 CPC), better results have been achieved in patients when the entire pouch has been resected and the normal large bowel is pulled through. This is because the pouch colon tissue investigated has demonstrated lack of normal spontaneous contractions despite maintaining acetylcholine- and histamine-induced contractility.[46] Also, fibrous tissue replaces the muscle layers of the pouch colon and affects motility adversely.[23,47] Hence, in cases of Type 1 and Type 2 CPC, the pouch colon tissue is salvaged, and a tubularized coloplasty is performed, with utilization of approximately 15 cm of tissue; this has been associated with favorable outcomes. Outcomes analyzed after tubularized coloplasty in a case report have shown normal bowel movements, adequate sensation, and a normal-sized neorectum on contrast enema.[48] Also, anorectal manometry has shown spontaneous rectal contraction and a complete rectoanal inhibitory reflex, which suggests that preservation of the native pouch colon is not contraindicated; however, this needs to be further investigated in a larger patient cohort. The defects in neuromusculature of pouch colon tissue are speculated to play a crucial role in postoperative dysmotility and redilatation of the pouch in cases when these morbidities are encountered. Therefore, the present evidence on functional outcome is variable and is probably related to the motility and histology of the retained colon.

CONCLUSION AND FUTURE DIRECTIONS

Surgical management at present focuses on the type of CPC to achieve optimal surgical results. The outcomes are variable, however, predicted with the present knowledge, based largely on the length of colon salvaged and the affected anorectal muscle complex. Future studies will be directed to investigate the etiology of CPC and details of colon histological characteristics, which are still unknown. Once the histological characteristics of the CPC are better understood, investigative studies will be necessary to correlate the histology with clinical outcomes. Greater awareness of these conditions and increased reporting in the literature will contribute toward the addition of anomalies that are associated with the spectrum of CPC.

Congenital segmental dilatation of the intestine

YOSHIAKI TAKAHASHI, YOSHINORI HAMADA, AND TOMOAKI TAGUCHI

INTRODUCTION

Congenital segmental dilatation (SD) of the intestine is a rare lesion defined as limited bowel dilatation with a 3- to 4-fold increase in size with an abrupt transition between the normal and dilated bowel and no intrinsic or extrinsic barrier distal to the dilatation. This condition is complicated by the obstruction of the intestines or chronic constipation from birth. It was first described in 1959 by Swenson and Rathauser[1] as "a new entity," which is distinct from Hirschsprung's disease in terms of the pathological finding of normal ganglion cells. Sine then, over 100 cases were reported in the world literature in 2006.[2] Thereafter, the number of case reports on patients with this condition has increased. Despite the large number of reports, the etiology of the disease remains elusive. Although the current study attempts to evaluate the roles of interstitial cells of Cajal, the enteric nervous system, and the smooth muscle in SD of the small bowel, the etiology has not been clarified.

We performed a nationwide retrospective cohort study on allied disorder of Hirschsprung's disease (ADHD) in Japan from 2000 to 2009.[3] SD was classified as an ADHD. We tried to collect all of the cases in which SD was diagnosed in Japanese authorized institutions in this period; as a result, we collected a total of 28 cases. The first and most recent retrospective cohort study of these cases was reported by Sakaguchi et al. in 2015.[4]

ETIOLOGY

The etiology of SD of the intestine remains unknown. Some of the hypotheses that have been proposed[1,5] include the following: abnormal tortuous vessels; vascular insufficiency during intussusception; disturbance during the splitting of the notochord from the endoderm; volvulus and kinking due to a long mesentery during the embryologic period; interruption of the continuity of the nerve fibers and the nerve plexus in the islands of ectopic tissue; entrapment by an omphalocele sac; and strangulation of the intestine in the umbilical ring during the early stage of development.

CLINICAL FEATURES AND DIAGNOSIS

We set the diagnostic criteria for SD based on previous reports (Table 70.1).[3]

The commonly dilated segments were the ileum (n = 14; 50%) and colon (n = 10; 35.7%) (Table 70.2).[4] Most of the described cases were discovered in neonates who presented with symptoms of intestinal obstruction in which the clinical picture was hard to differentiate from more common causes of occlusion, such as intestinal atresia, Hirschsprung's disease, meconium ileus, intestinal duplication, and midgut volvulus (Figure 70.1). Consequently, they were diagnosed with this condition when they were neonates or infants. The symptoms in children vary. The most frequent symptom beyond the infant period is gastrointestinal bleeding and anemia due to the ulceration of the dilated segment, which becomes more profuse in the presence of heterotopic gastric mucosa.[2,6–9] Rarely, the patient may present with peritonitis due to perforation of the dilated segment.[8,10] Our report showed that the onset of the disease most frequently occurred in the neonatal period (n = 18; 64.3% [including 7 cases that were prenatally diagnosed]) (Table 70.3). The common symptoms were abdominal distension and vomiting. One case had a family history of SD in cousins, and one case had a family history of severe constipation in brothers.[4]

Because the symptom is not specific and the definitive diagnosis is difficult, SD is usually diagnosed incidentally during surgery (Figure 70.2). However, the anomaly can also be suspected or diagnosed preoperatively on the basis of radiologic findings.[11,12] The classic feature of SD on plain radiographs is the marked SD of the bowel loop, with or without an air-fluid level. Contrast enema studies are often useful for confirming SD of the bowel loop.[12] In SD of the colon, the contrast enema findings are very similar to those of Hirschsprung's disease, but the two conditions can be

Table 70.1 Criteria for diagnosis of segmental dilatation of the intestine

a. Limited bowel dilatation with a three-to fourfold increase in size
b. An abrupt transition between the dilated and normal bowel
c. No intrinsic or extrinsic barrier distal to the dilatation
d. A clinical picture of intestinal occlusion or subocclusion
e. A normality of the neuronal plexus
f. Complete recovery after resection of the affected segment

Table 70.2 Location of dilatation

Ileum	14 cases (50.0%)
Colom	10 cases (35.7%)
Jejunum	3 cases (10.7%)
Duodenum	1 case (3.6%)

Table 70.3 Onset period

Neonatal	18 cases (64.3%)
Infancy	6 cases (21.4%)
Childhood	2 cases (7.1%)
Over 6 years old	2 cases (7.1%)

Figure 70.1 Plain abdominal x-ray showed a dilated bowel (arrow) in the front of the abdomen. Air-fluid level was prominent in upright position.

differentiated by anorectal manometry. Additionally, histochemical studies demonstrate that there is no proliferation of the cholinergic nerve fibers of the rectal mucosa.

PATHOLOGY

The histopathological findings are the most important diagnostic criteria. The presence of ganglion cells that are normal in number and morphology is one of the criteria for the differential diagnosis. Microscopy can reveal some anomalies, essentially a hypertrophic muscular layer and a heterotopic mucosa that can include esophageal, gastric, or pancreatic tissue. Hypertrophy of the circular and longitudinal layers of the muscularis propria in the dilated segment is evident in older infants/children and is probably an acquired functional adaptation that occurs secondarily to chronic fecal distension.[13,14]

In our report, decreased numbers of ganglion cells or immature ganglion cells were found in three cases, and abnormal muscle layers were found in three cases. Ectopic pancreatic or gastric tissues were found in one case each. Immunohistological investigations showed decreasing c-kit-positive cells in the dilated segment in two of three cases.[4] Some case reports of SD detected decreasing c-kit-positive cells in the dilated segment.[15–17] In some cases, other immunohistological investigations, such as S-100 or MAP5, assisted in the diagnosis of SD.[18] Furthermore, a recent study reported the dislocation of the myenteric plexus within the circular muscle layer (Figure 70.3).[19] We experienced a similar case. Precise histological and immunohistological investigations in future cases of SD might provide more detailed information about its etiology.

TREATMENT

The treatment of SD depends on the clinical condition of the patient, the presentation, the surgeon's experience in dealing with such malformations, and the association with other malformations. The definitive surgery is resection of the involved segment and end-to-end anastomosis with/without proximal colostomy.[5,20,21] In the case of patients who are critically ill (such as patients with perforation or chromosomal abnormalities), an ileostomy can be fashioned

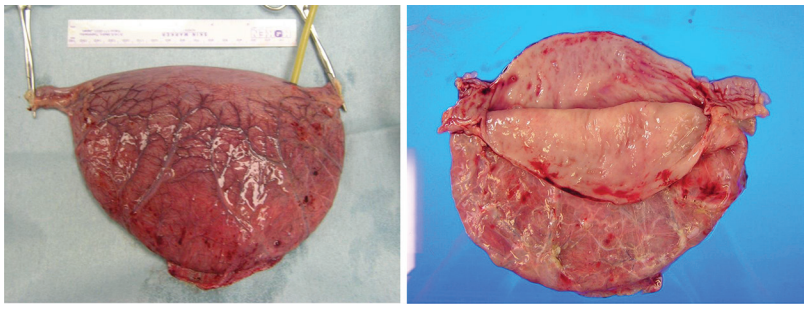

Figure 70.2 Macroscopic finding of resected dilated bowel. Both ends were normal in size.

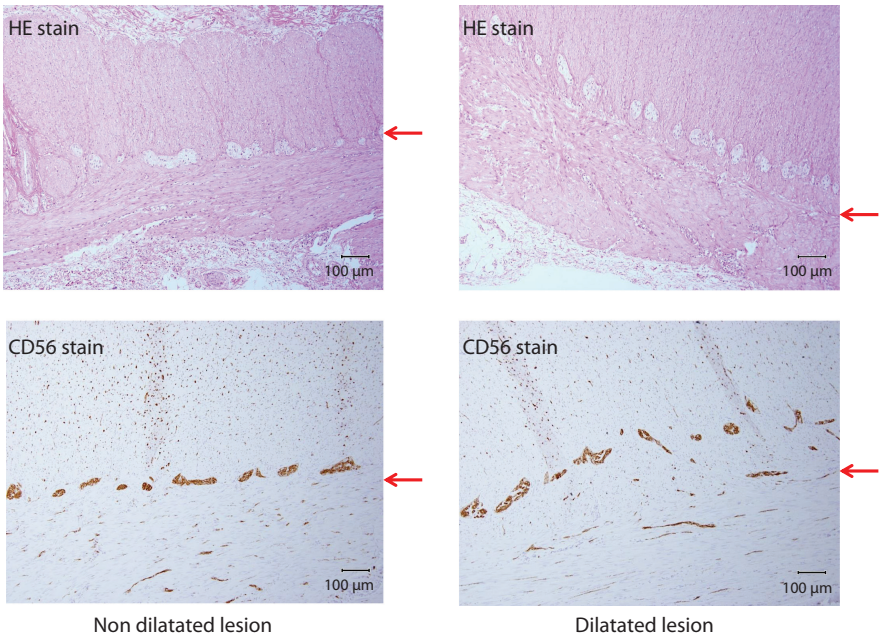

Figure 70.3 Myenteric plexus shifted to the circular muscle layer at the dilated lesion, but not at the nondilated lesion. Arrows showed intermuscular zone.

without excision of the SD.[22] In the case of associated anorectal malformations, stoma formation is always recommended for anorectoplasty in the second stage. A covering ileostomy was also fashioned due to the presence of multiple colonic anastomoses and rectal atresia.[22]

Some reports recommend the use of laparoscopic procedure in the surgical treatment of SD.[7] Laparoscopy was found to be a reliable diagnostic tool and is a minimally invasive procedure that provides safe and superior cosmetic results.[7]

PROGNOSIS

Most patients who undergo surgery for SD experience an uncomplicated postoperative course. The survival rate is excellent unless other serious complications or anomalies are present.

In Japan, SD patients respond favorably to surgical resection. One male patient who underwent ileocecal resection for cecal SD at 9 years of age died at 12 years of age from catheter-related sepsis and liver dysfunction. The patient required parenteral nutrition for 3 years after resection of the dilated bowel; thus, the case might have been complicated by chronic idiopathic intestinal pseudo-obstruction. Excluding this case, the survival rate of SD was 100%.[4]

In our experience, the initial diagnosis was SD of the transverse colon. After resection, gastric dilatation and megacolon appeared. Small intestine perforation due to abnormal dilatation arose several years later, and the final diagnosis was chronic idiopathic intestinal pseudoobstruction (CIIP). Thus, SD cases require careful follow-up. If there is a recurrence of intestinal dilation after resection, we should consider CIIP.

ACKNOWLEDGMENTS

The authors wish to acknowledge Dr. K. Ohama and Dr. N. Ishikawa for offering the data of a case. And we thank Mr. B. Quinn for an English revision.

Intussusception

SPENCER W. BEASLEY

PRENATAL INTUSSUSCEPTION

Prenatal intussusception is a recognized cause of intestinal atresia.[1,2] The presentation is that of a bowel obstruction at birth. Preoperative evaluation usually fails to yield a definite diagnosis,[1] and the diagnosis is usually made at laparotomy.[2]

Prenatal intussusception may be associated with isolated or transient fetal ascites,[3,4] meconium peritoritis,[5] or a meconium pseudocyst.[6] Some cases are due to a Meckel's diverticulum.[7] Prenatal intussusception results in an ileal atresia following vascular impairment, necrosis, and resorption of the intussusception, irrespective of the underlying lesion causing the intussusception.[4,6,8] Sonographic findings of fetal intestinal intussusception include a "target-like" lesion (a round hyperechoic area of fetal bowel mucosa surrounded by a relatively hypoechoic ring of bowel wall), dilated bowel loops, and abdominal calcifications.[9] Sometimes, the clues to prenatal intussusception have been present on antenatal ultrasonography, so perhaps not surprisingly, the infant presents at birth with abdominal distension and features of a bowel obstruction.[10]

NEONATAL INTUSSUSCEPTION

Although intussusception is common in the first year of life, it is rare in neonates and premature infants,[3,11] accounting for fewer than 1% of cases. Extremely rarely, intussusceptions may be multiple,[11,12] which is notable because in this situation, there is generally no obvious pathological lesion at each lead point.

Generally speaking, it is reasonable to assume that when intussusception occurs in a neonate, there is a pathological lesion at the lead point, such as a duplication cyst, inverted Meckel's diverticulum, jejunal polyp,[10] or ileal polyp.[13] Even beyond the neonatal period, in any infant under 3 months of age, it is much more likely that there is a pathological lesion at the lead point than when it occurs later in the first year of life.[1,14] This is in contrast to the typical age of idiopathic intussusception (in which there is no obvious pathological lesion causing the intussusception), which is between 3 and 12 months, with a peak incidence at about 5–6 months.

The rotavirus vaccine

An early rotavirus vaccine (Rotashield) was withdrawn from the market because of its association with intussusception. Newer live, oral, attenuated rotavirus vaccines (Rota Teq and Rotarix) were believed to have no increased risk of intussusception,[15,16] but the latest data from the Centers for Disease Control and Prevention[17] suggest that 1 in 20,000–100,000 US infants who get rotavirus vaccine develop intussusception within a week of being given the vaccine. Rotarix is normally administered to infants at 6–24 weeks of age. The advantages of the vaccine still far outweigh the risks, but parents should be warned of the possibility of intussusception following vaccination, and physicians should be suspicious if symptoms consistent with intussusception occur shortly after vaccination.

CLINICAL ASSESSMENT

The key features of intussusception are those of a bowel obstruction. When intussusception occurs in premature infants or in the neonatal period, its presentation may mimic neonatal necrotizing enterocolitis: the infant develops bile-stained vomiting, increased nasogastric aspirates, blood in the stools, and intestinal dilatation—but without evidence of intramural gas (pneumatosis intestinalis) that is pathognomonic of necrotizing enterocolitis.[18] It is not surprising that diagnostic confusion with necrotizing enterocolitis can lead to delay in appropriate treatment.[19] Similarly, in the neonate, the combination of bowel obstruction and rectal bleeding may lead to confusion with malrotation and volvulus; given the rarity of the condition in this age group, the diagnosis is often made only at operation.

In the older infant, vomiting, lethargy, pallor, and colic are the most common symptoms.[20] In long-standing cases, the infant may appear shocked and septicemic, with abdominal distension. Where abdominal distension and tenderness are

not pronounced, an abdominal mass may be palpable, and there may be evidence of blood mixed with the stool on rectal examination. Transanal protrusion of an intussusceptum is rare, but when it occurs, it may be confused with rectal prolapse and is associated with significant morbidity.[21]

NONOPERATIVE TREATMENT

Indication for enema

When a diagnosis of intussusception is suspected and there is no clinical evidence of necrotic bowel (i.e., peritonitis or septicemia), reduction of the intussusception by gas enema should be attempted.[22] As alternatives, hydrostatic reduction under ultrasonographic control,[23] or in institutions where gas enemas are not available, a barium enema, may be employed. Duration of symptoms, radiological evidence of small bowel obstruction,[24] and the position of the apex[25] per se are not contraindications to attempted enema reduction but can have some value in predicting the likelihood of successful reduction.

Unfortunately, a contrast enema in the neonate is diagnostic in relatively few cases, mainly because the intussusception often does not extend through the ileocecal valve, which often remains competent such that contrast cannot enter the ileum. Abdominal ultrasonography is a more reliable way to make the diagnosis (Figure 71.1) and, in many centers, is performed routinely where intussusception is suspected.[23] Routine plain radiology of the abdomen is unnecessary[26] and tends to be obtained only when the possibility of intussusception has not be considered. Ultrasonography is a more sensitive and more specific diagnostic tool.

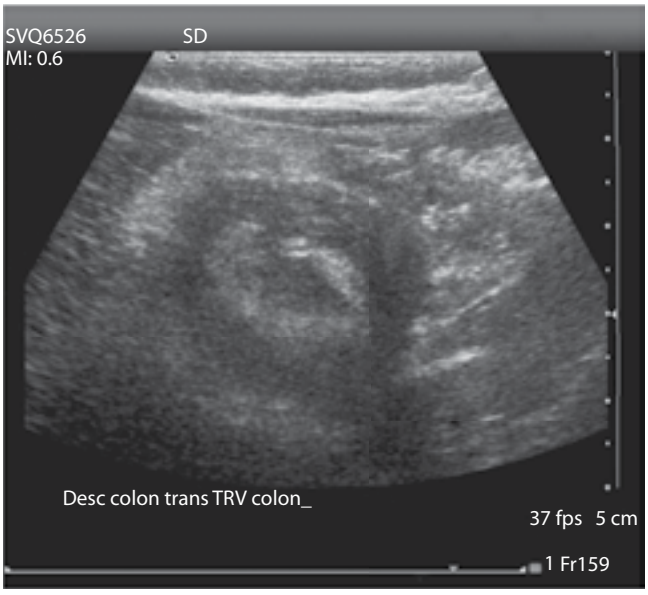

Figure 71.1 Ultrasonographic appearance of intussusception with the concentric rings of the intussusceptum within the intussuscipiens.

Preparation for gas enema

There is considerable evidence that the gas enema is more effective and safer than the barium enema for reduction of intussusception that extends beyond the ileocecal valve (Figure 71.2).[27–29] Ideally, the gas enema should be performed in a pediatric surgical institution by an experienced pediatric radiologist in the presence of a pediatric surgeon.[27] An intravenous line should be inserted and rehydration commenced before undertaking the enema. The child should be placed on a warming blanket during the procedure to prevent heat loss.

Technique of enema reduction

Gas (usually oxygen from a wall supply) is pressure-controlled and run into the colon through a Foley catheter, which has been inserted through the anal canal, as with a conventional barium enema reduction.[27] The infant lies prone with buttocks taped and squeezed tightly together by the radiologist to avoid air leakage. The upper limit of pressure can be controlled by a manometer, and the entire procedure is performed under continuous fluoroscopic control (Figure 71.3).

Cessation of gas enema

Flooding of the small bowel with gas signifies a complete reduction of the intussusception (Figure 71.4). If free intraperitoneal gas is observed, the enema should be ceased immediately. Very rarely, a tense pneumoperitoneum ensues (if there is delay in recognizing the complication) and may need decompression with an angiocath needle through the abdominal wall. Gas reduction tends to occur more rapidly than barium reduction. Both techniques have a similar recurrence rate,[30] but the perforation rate may be more common after a gas enema than a barium enema.[31,32]

Delayed gas enema after partial reduction

Where the initial attempt at reduction has been unsuccessful but there has been partial reduction, and the infant remains in good clinical condition, repetition of the gas enema after 2–3 hours is likely to be successful in about 50% of cases.[33] Where there has been further (but incomplete) reduction after the second attempt, a third attempt may be successful in around another 50%.

INDICATIONS FOR SURGERY

Clinical evidence of peritonitis or septicemia is an absolute indication for surgery, as it signifies that dead bowel is likely to be present and resection is required (Table 71.1). Other indications for surgery include failure of repeated gas enemas to reduce the intussusception or (in the case of neonates) early recurrence of intussusception after a successful enema where the presence of a pathological lesion at the lead point is likely. Occasionally, a pathological lesion at the lead

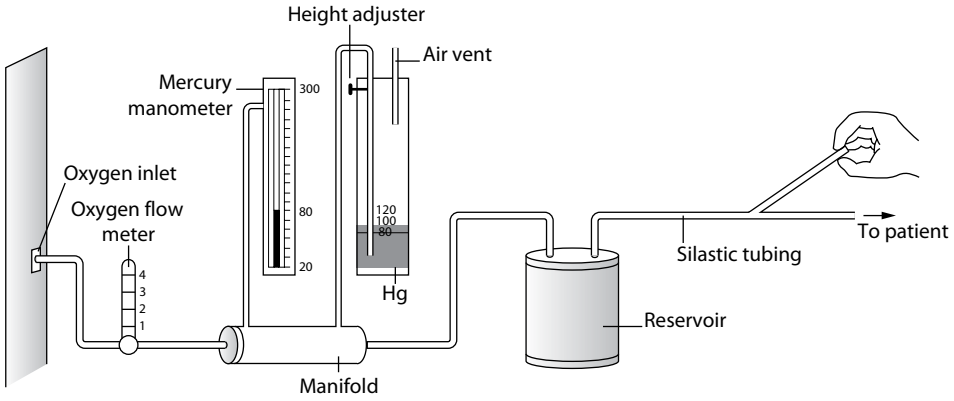

Figure 71.2 Schematic representation of the apparatus used to achieve gas (oxygen) reduction of intussusception.

Figure 71.3 Gas reduction of intussusception: the pressure-controlled oxygen runs through the anus and outlines the intussusceptum, in this patient, encountered in the transverse colon.

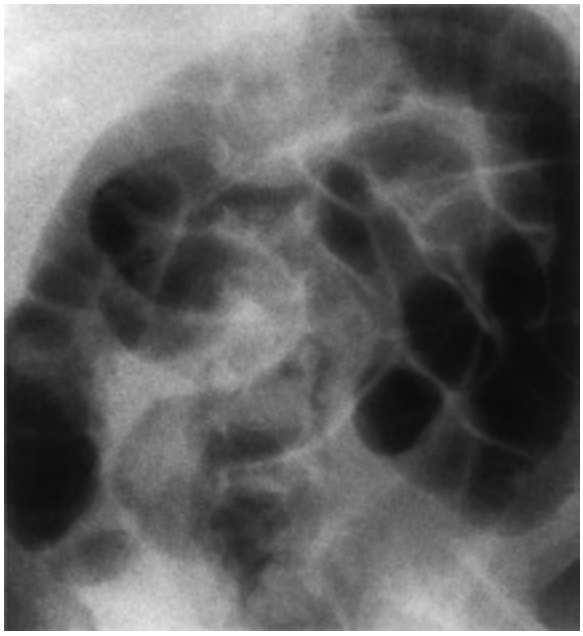

Figure 71.4 Sudden flooding of the small bowel signifies complete reduction of the intussusception.

Table 71.1 Indications for surgery

Clinical evidence for dead bowel, i.e., peritonitis, septicemia
Failure of (repeated) enema reduction
Early or multiple recurrences (relative indication)
Evidence of pathological lesion at the lead point that requires resection

point may be seen during attempted enema reduction, and typically, the intussusception cannot be reduced by enema when a pathological lesion is present. In the neonate who presents with an established bowel obstruction, the diagnosis is made when the intussusception is discovered at the time of laparotomy or laparoscopy. Surgical management involves resection of nonviable bowel and primary anastomosis. Until recent years, the mortality rate was over 20%,[11] largely because of delay in diagnosis, but it is now believed to be much lower.

Preparation for surgery

Prior to induction of general anesthesia, a nasogastric tube is inserted to empty the stomach. Prophylactic antibiotics are given intravenously at induction. The infant is paralyzed and intubated. A warming blanket must be used to prevent excessive heat loss, and temperature is monitored with a rectal or midesophageal probe. An oximeter monitors oxygen saturation. Following the procedures on the Surgical Safety Checklist ensures that every member of the team is fully informed and prepared prior to the surgery commencing.

SURGICAL TECHNIQUE

Approach

The classical approach is through a right supraumbilical transverse incision, dividing the ventral abdominal wall muscles in the line of the incision (Figure 71.5). The peritoneum is opened. This gives good exposure, irrespective of the length of intussusception. Free peritoneal fluid is aspirated, and the bowel is delivered into the wound.

Alternatively, a laparoscopic approach using a 5 mm umbilical port for the telescope and two 3 mm or 5 mm working ports is employed. The abdominal wall of the neonate is thin enough that a small incision may allow the 3 mm instruments to be introduced directly without a port. A laparoscopic approach may be difficult in the presence of marked gaseous distension of the bowel, necessitating conversion to an open approach.

Manual reduction

The intussusception is carefully reduced by manipulation of the intussusceptum within the intussuscipiens in a proximal direction (Figure 71.6). This is performed by gently squeezing the bowel between the fingers and in the cup of the hand. Time must be allowed to enable edema of the mesentery and bowel to dissipate. The intussusception is most difficult to reduce in the region of the ileocecal valve. Care must be taken to avoid splitting the serosa. A similar technique is used in the laparoscopic approach, but reduction is completely reliant on instrumental manipulation.

Check for a pathological lead point

After full reduction of the intussusception, a dimple at the lead point is a common sight and in itself does not represent a pathological lead point. Look for evidence of a duplication cyst, inverted Meckel's diverticulum, or another lesion at the lead point, because if these are present, they should be resected.

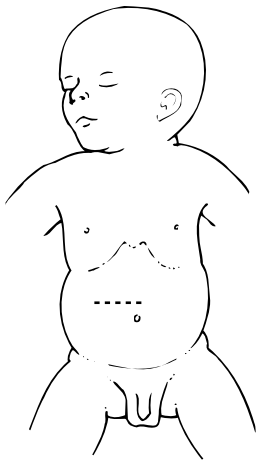

Figure 71.5 Right supraumbilical transverse incision.

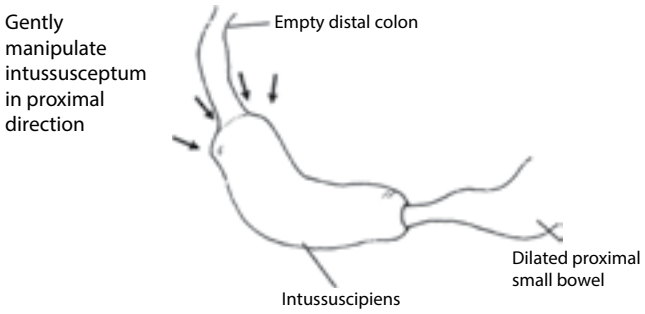

Figure 71.6 Gentle pressure on the distal limit of the intussusception coerces the intussusceptum proximally. Pulling on the bowel as it enters the intussuscipiens is not advised, as it tends to be more traumatic and less efficient at reducing the intussusception.

Technique of resection

The indicators for resection are shown in Table 71.2. The aim should be to remove as little viable bowel as possible (Figure 71.7). The small bowel mesentery is ligated and divided, and the bowel at the edges of resection is divided with scissors. An all-layers 4-0 Vicryl or similar absorbable suture is used to perform an end-to-end anastomosis. The defect in the mesentery is closed to prevent later internal herniation.

Closure

The peritoneal cavity is irrigated with warm saline. The peritoneum and posterior rectus sheath and anterior rectus sheath are closed with continuous 3-0 sutures. The skin is closed with an absorbable subcuticular suture such as a 5-0 Monocryl suture. No drainage is required. When a laparoscopic approach has been used, the 5 mm umbilical wound should be sutured, but the 3 mm working ports do not need to be closed with sutures, and the risk of incisional hernia is low.

Postoperative instructions

A nasogastric tube is usually not necessary unless there has been severe obstruction or a prolonged ileus is anticipated.

Inguinal hernia

THAMBIPILLAI SRI PARAN AND PREM PURI

INTRODUCTION

Inguinal hernia is one of the most common surgical conditions in infancy, with a peak incidence during the first 3 months of life. The incidence of hernia is much higher in premature infants, who are surviving in increasing numbers with improved intensive care management, and subsequently increasing the overall incidence. The diagnosis of inguinal hernia can be made without major difficulty in newborns. Early infancy carries a particularly high risk of incarceration of inguinal hernias. As a consequence, early surgical repair is advocated in a population in which there are additional surgical and anesthetic risks.

ETIOLOGY

Almost all inguinal hernias in the newborn are indirect in nature, through a patent processus vaginalis; direct inguinal hernias are exceedingly rare at this age.[1] The processus vaginalis is an outpouching of the peritoneum through the inguinal canal that is first seen during the third month of intrauterine life. In male infants, the processus accompanies the gubernaculum and the testis during their descent through the inguinal canal and reaches the scrotum by the seventh month of gestation. In the female, the processus extends along the round ligament. Obliteration of the processus vaginalis commences soon after the descent of the testis is completed and continues after birth. Most infants have a patent processus vaginalis several months after birth. Patency has been reported to be 80%–94% in the newborn period, 57% in the 4–12-month age group, and 20% in adulthood[2]; this patency is not equivalent to an inguinal hernia, and most times it has no clinical relevance.

EPIDEMIOLOGY

The incidence of congenital indirect inguinal hernia in full-term neonates is 3.5%–6.2% in males and 0.74% in females.[3,4] The incidence of inguinal hernia in preterm infants is considerably higher and ranges from 9% to 11%.[5] The incidence approaches 60% as birth weight decreases to 500–750 g.[2] Inguinal hernia is more common in males than in females. Most series report a male preponderance over females ranging from 5:1 to 10:1.[6] Of all inguinal hernias, 60% occur on the right side, 25%–30% on the left, and 10%–15% are bilateral.[2,7] Bilateral hernias are more common in premature infants and are reported to occur in 44%–55% of patients.[5,8,9] The reported risk of a metachronous contralateral hernia is 7%–10%.[10–13] There is a higher familial incidence, and inguinal hernia has been observed with increasing frequency in twins and siblings of patients.[14] There is no geographic or racial predominance reported in the literature.

ASSOCIATED CONDITIONS

There is an increased incidence of inguinal hernia in patients with the following conditions:

- Prematurity
- Undescended testis
- Ventriculoperitoneal shunts[15,16]
- Peritoneal dialysis[17,18]
- Cystic fibrosis
- Increased abdominal pressure[19] secondary to meconium ileus, necrotizing enterocolitis, chylous ascites, tight closure of gastroschisis, omphalocele
- Bladder exstrophy[20,21]
- Connective tissue disorders such as cutis laxa,[22] Ehlers–Danlos, and Marfan syndromes or Hurler–Hunter mucopolysaccharidoses[23]

CLINICAL FEATURES

Inguinal hernia can be diagnosed prenatally by ultrasonographic screening.[24] In the newborn, the presenting feature is a bulge in the groin, which increases in size with crying and which is usually noticed by the parent. This bulge may disappear spontaneously when the patient is quiet and

relaxed, but sometimes it remains visible and palpable for hours causing obvious discomfort and sometimes vomiting. When the lump in the groin is reduced, it is usually possible to feel thickening of the structures of the cord due to a hernial sac. A reliable clinical history along with a palpable thickened cord is highly suggestive of inguinal hernia, and alone is sufficient to proceed to surgery, as clinical demonstration of the bulge may prove difficult at routine consultation.

In girls, the inguinal bulging is intermittently felt in the groin and is usually less obvious. Occasionally a tender, nonreducible, ovoid-shaped mass, corresponding to the ovary, sliding within the sac can be palpated; this could easily be mistaken for a swollen inguinal lymph node.

Some premature infants with previous apneic episodes have been reported to stop having them after inguinal hernia repair. The obvious interpretation is that there can be some association between both clinical conditions.[25] Although this eventuality is exceedingly rare, acute inflammation of the appendix within the hernial sac has been reported in premature and full-term newborns.[26–29]

MANAGEMENT OF INGUINAL HERNIA

The treatment of inguinal hernia is surgery and, in our opinion, there is no place for the use of trusses or other so-called conservative procedures, even in low birth weight (LBW) infants.[30] The ideal time for surgery is as soon as possible after the diagnosis has been made not only because of the high risk of incarceration[31] but also because it has been shown that comfort and weight gain of premature infants with inguinal hernias improve after repair.[32] Nowadays, most inguinal hernia operations are done as day-case procedures.[33] Premature infants and children with cardiac, respiratory, or other conditions have an increased risk of anesthetic complications and may need overnight observation for apnea. However, some authors consider it reasonably safe to operate on these patients on a day-case basis.[34,35]

ANESTHESIA

General anesthesia with endotracheal intubation is preferred in small infants. Premature infants undergoing surgery have an increased risk of life-threatening postoperative apnea.[36] The use of spinal anesthesia in LBW infants undergoing inguinal hernia repair is associated with a lower incidence of postoperative apnea.[37,38]

OPEN INGUINAL HERNIOTOMY

Inguinal herniotomy is the procedure employed in the treatment of congenital persistence processus vaginalis. The operation consists of simple ligation of the hernial sac without opening the inguinal canal.

Position: The infant is placed in the supine position on a heating blanket.

Incision: A 1.5 cm transverse inguinal skin crease incision is placed above and lateral to the pubic tubercle (Figure 72.1a).

Exposure of external ring: Hemostats are placed on subcutaneous tissue, which is cut or spread until the cord is seen to emerge from the external ring (Figure 72.1b,c).

Separation of sac: The cord is isolated over a mosquito forceps with blunt dissection around the cord. The external spermatic fascia and cremaster are separated along the length of the cord by blunt dissection. The hernial sac is seen as a glistening ivory-colored structure and is gently separated from the vas and vessels (Figure 72.1e). A hemostat is placed on the fundus of the sac, in case of incomplete hernial sacs, to aid the separation. In complete hernial sacs, it may be necessary to open the sac before the separation can be completed safely off the vas and vessels.

Herniotomy: The sac is twisted so as to reduce its content into the abdominal cavity. The spoon can be used to keep vas and vessels away from the neck of the sac. The sac is transfixed with a 4-0 absorbable suture at the level of the internal ring, which is marked by an extraperitoneal pad of fat (Figure 72.1b). The part of the sac beyond the stitch is usually excised; but there are no obvious advantages of removing the distal part of the sac after its division and transfixion, and the operation should remain as simple as possible.[39] With large preterm neonatal hernias, it may be necessary to partially tighten the deep ring around the cord structures with one or two absorbable interrupted sutures to reduce recurrence. In girls, the operation is more straightforward since there are no vas or vessels and the external ring can be closed after excising the sac. However, it is prudent to open the sac to exclude any gonadal before placing the transfixation suture.

Closure: Subcutaneous tissues are approximated using one or two 4-0 absorbable interrupted stitches (Figure 72.1g), and the skin is closed with a 5-0 absorbable continuous subcuticular suture (Figure 72.1h). A recent alternative is the use of cyano-acrylate adhesives for approximating the skin edges. A small dressing can be applied over the wound if necessary. At the end of the operation, the testis, always tractioned upward during operative maneuvers, must be routinely pulled back into the scrotum to avoid iatrogenic ascent.[40]

LAPAROSCOPIC INGUINAL HERNIA REPAIR

Laparoscopic hernia repair in infancy has gained support over the last decade. In recent years, several authors have reported that laparoscopic hernia repair in infants is feasible, safe, and effective.[41–44] Laparoscopic percutaneous techniques utilize just one port as opposed to three, and appear to work well in selected children.[45] Some authors have reported up to 20% contralateral herniotomies with the laparoscopic approach[39] and highlight the increased intervention based on appearance of patent processus, which is known not to cause any hernias in vast majority of children. Though some surgeons prefer the laparoscopic approach in

very small infants and achieve excellent results, cosmesis should not be put ahead of safety in preterm and small birth weight children.

CONTRALATERAL EXPLORATION

We don't routinely explore the contralateral side in newborns presenting with unilateral hernia. Only around 10% of these children will subsequently proceed to develop a clinically apparent inguinal hernia on the other side.[11–13] In premature babies who have been shown to have a high incidence of bilateral hernia, which ranges from 44% to 55% according to different authors,[5,8,9] there may be a role for bilateral exploration.

IPSILATERAL ORCHIDOPEXY

Two-thirds of undescended testes detected at the time of newborn inguinal hernia repair appear to descend naturally with time.[40] If the testis remains high above the scrotal

pouch after the herniotomy or if the gubernaculum has been divided in a particularly difficult neonatal hernia repair, we feel that the testis should be pexed within a scrotal pouch. Otherwise, testis can be left within the high scrotal region and observed over a period of time.

POSTOPERATIVE MANAGEMENT

Adequate postoperative analgesia is achieved by either caudal block or ilioinguinal and iliohypogastric nerve block, which is administered either before or at the end of operation. Feeding is resumed as soon as the infant is awake. Most patients can be discharged home the same day. Postoperative apnea is a well-known risk of inguinal hernia operation in premature infants.[46] Although most episodes of postoperative apnea in these babies occur in the first 4 hours following the end of the procedure,[47] they are often admitted for 24 hours for observation in order to manage this complication.[48] Postoperative apnea is inversely correlated with gestational and postconceptual ages,[49] but absolute weight at operation and previous respiratory dysfunction are apparently the best independent variables to be correlated with such risks.[50]

COMPLICATIONS OF INGUINAL HERNIOTOMY

The overall complication rates after elective hernia repair are low at about 2%,[51] while these are increased to 8%–33% for the incarcerated hernias requiring emergency operations.[5,51]

Complications of inguinal hernia repair include the following:

- *Hematoma*—Can be avoided with meticulous attention to hemostasis. It is rarely necessary to evacuate wound, cord, or scrotal hematoma.
- *Wound infection*—Low risk and should not exceed 1%.[3,47,52]
- *Gonadal complications*—Occur due to compression of the vessels by incarcerated viscera. Though large numbers of testes look nonviable in patients with incarcerated hernia, the actual incidence of testicular atrophy is low[53] and therefore, unless the testis is frankly necrotic, it should not be removed.
- *Intestinal resection*—This is necessary in about 3%–7% of patients in whom the hernia is not reduced, and it may cause some additional morbidity corresponding to resection itself and contamination of the field.[5]
- *Iatrogenic ascent of the testes*—This event is relatively rare since slightly more than 1% of patients operated upon for inguinal hernia during infancy subsequently required orchidopexy.[54] This complication is probably due to entrapment of the testis in the scar tissue or failure to pull it down into the scrotum at the end of the operation and to maintain it there.
- *Recurrence*—The acceptable recurrence rate for inguinal hernia repair is less than 1%, but when the operation is performed in the neonatal period, this complication can occur in up to 8%.[52,55] The factors that predispose to recurrence are ventriculoperitoneal shunts, sliding hernia, incarceration, and connective tissue disorders.[56] Recurrence may be indirect or direct. Indirect recurrence is due to either failure to ligate the sac at high level, tearing of a friable sac, a slipped ligature at the neck of the sac, missed sac, or wound infection. Direct hernia may be due to inherent muscle weakness or injury to the posterior wall of the inguinal canal.
- *Mortality*—In a present-day situation, the mortality rate of inguinal hernia operation should be zero.

INCARCERATED INGUINAL HERNIA

Incarceration occurs when the protruded peritoneal contents within the hernial sac are constricted at its neck and cannot be easily reduced into the abdominal cavity. Strangulation occurs when there is vascular compromise to the contents of the sac because of prolonged and complete constriction at its neck. The contents of the hernial sac may consist of small bowel, appendix, omentum, or ovary and fallopian tube. If there is delay in treatment, incarceration rapidly progresses to strangulation and can lead to intestinal necrosis and even fecal fistula.[57]

The incidence of incarceration in neonates and young infants is reported to vary between 24% and 40%.[3,53,58] The incarceration rate is much higher in premature infants compared with full-term infants. Testicular infarction has been reported in up to 30% of infants younger than 3 months of age with incarcerated inguinal hernia,[59] and testicular atrophy following emergency operation for incarceration ranges between 10% and 15%. However, testicular volume in a group of children who had incarcerated inguinal hernia reduced by taxis during infancy and subsequently had elective herniotomy was not significantly different from age-matched controls, suggesting that this risk has been overemphasized.[53] Ovarian infarction is also possible after incarceration in females,[5] and vaginal bleeding has been reported in an infant after uterine incarceration in the hernial sac.[60] The risks of gonadal damage when the slided ovary cannot be reduced justify the fact that most surgeons advise prompt operation in these children.[33]

The risk of incarceration and clinical symptoms of partial obstruction of small bowel within the hernial sac must be balanced with the overall condition of the neonate in deciding the optimal time for surgery. Very premature infants with significant pulmonary compromise who are within a hospital environment can be safely observed till term or ready for discharge home, with intermittent reduction of hernial contents.

Diagnosis of incarcerated inguinal hernia

A newborn with incarcerated inguinal hernia usually presents with irritability, vomiting, a moderately distended abdomen, and a tender groin lump (Figure 72.2). Occasionally, the infant may pass blood per rectum. Local

Figure 72.2 Large incarcerated right inguinal hernia in a 1-day-old infant. The hernia was reduced by taxis and herniotomy performed 2 days later.

Figure 72.3 Supine abdominal film in a 10-day-old infant who presented with an irreducible lump in the right groin shows distended bowel loops extending into the right inguinal hernia.

examination reveals a tense, tender lump in the groin, the upper margin of which is usually not well defined. The ipsilateral testis may be normal or swollen and hard due to vascular compromise. Rectal examination usually is not necessary, but, if done, the contents of the hernia can be palpated at the internal ring.

The diagnosis of incarcerated inguinal hernia is usually made on clinical grounds. Abdominal radiographs may occasionally show bowel gas within the lump in the groin and confirm the diagnosis (Figure 72.3). If intestinal obstruction is present, plain abdominal films will show dilated loops of bowel with fluid levels. Ultrasonography can aid the diagnosis in some difficult cases as outlined below within the differential diagnosis.[61]

Differential diagnosis of incarcerated hernia

ENCYSTED HYDROCOELE OF THE CORD

Hydrocele of the cord or cyst of canal of Nuck is difficult to differentiate from incarcerated hernia. It may be possible to get above a hydrocoele and is nontender. Transillumination is not a reliable sign in infants, as bowel wall is very thin and is usually transilluminant. However, there will be no preceding history of reducible swelling reported by parents, and the child remains asymptomatic with no obvious signs of discomfort. Ultrasound is helpful in distinguishing this condition from an obstructed hernia.

INGUINAL LYMPHADENITIS

Usually the swelling is more laterally oriented on examination, and a thorough inspection of the area of drainage will, at most times, reveal the source of infection. The cord and testes are found to be normal.

TORSION OF THE TESTES

In a scrotal testicular torsion, it is possible to get above the swelling. The testis is tender and slightly higher than on the other side. When there is an empty scrotum detected with a tender inguinal swelling on that side, torsion of an undescended testis must be suspected. Whether torsion of an undescended testis or an incarcerated hernia is suspected, urgent surgical exploration is necessary.

Management of incarcerated hernia

In a stable patient, there is no doubt that the preferred treatment for incarcerated hernia is reduction. This policy of nonoperative reduction is based on the following facts: the likelihood of reducing strangulated bowel in infants is extremely rare, and the complication rates are higher with emergency operations for irreducible hernia.[51]

The infant is placed in the Trendelenburg position, which helps to relieve the edema and allows mild traction of the hernial contents. Adequate sedation is given to the infant so as to relax the abdominal muscles. If the hernia is not reduced within 1 hour with these measures, an attempt is made to reduce it with gentle taxis, where constant gentle pressure is applied on the fundus of the sac in the direction of the cord. The vast majority of incarcerated hernias reduce with these nonoperative techniques. After the hernia is reduced, the infant is kept in the hospital and observed. Elective operation is carried out after 24–48 hours, when local edema has subsided.

Failure to reduce a strangulated or incarcerated inguinal hernia is an indication for emergency operation. In girls, when the ovary is not reducible, at least half of the surgeons in a recent US survey advice emergency operation.[33]

Surgery for obstructed, irreducible inguinal hernia

Infants need to be stabilized prior to surgery. Nasogastric suction and correction of fluid and electrolyte imbalance are undertaken, and antibiotics are given, but this period should be kept to a minimum. The patient is anesthetized.

SPONTANEOUS REDUCTION WITH NO ISCHEMIC BOWEL

If the hernia is spontaneously reduced after the induction of general anesthesia, the sac is opened and the peritoneal cavity is inspected as much as possible. Intestinal ischemia or necrosis will usually be accompanied with blood-stained peritoneal fluid. If there is no suspicion of bowel ischemia or only a mild suspicion exists, herniotomy is performed as described above. Usually the procedure is more difficult due to the surrounding edema and increased friability of the hernial sac. The risk of injury to vas and vessels is high, and this must be borne in mind during the dissection.

SPONTANEOUS REDUCTION WITH ISCHEMIC BOWEL

If there is any suspicion of bowel necrosis, the bowel must be inspected fully. Occasionally this may be possible through the hernial sac opening. If this cannot be achieved safely, without damage to vas or testicular vessels, then a laparotomy is warranted. This can be achieved either through a separate right iliac fossa transverse muscle cutting incision or by increasing the size of the herniotomy incision laterally, and then by retracting the skin wound superiorly to enable a muscle cutting/splitting laparotomy wound.

NO SPONTANEOUS REDUCTION WITH OR WITHOUT ISCHEMIC BOWEL

If the bowel does not reduce spontaneously when the patient is anesthetized, no attempts are made to reduce the hernia. The sac is opened and the contents are examined. If the bowel is viable, it is reduced. In case of difficulty in reducing the contents, the internal ring is either dilated or split superiorly. On the other hand, if viability of the bowel is questionable, it is delivered out and warm saline soaks are applied. The intestine is examined after 5–10 minutes. If its color returns to normal with adequate perfusion, visible peristalsis, and palpable mesenteric arterial pulsations, then the intestine is returned to the abdomen and herniotomy is completed. If the bowel is nonviable, resection and anastomosis are performed, either through the same incision or through a separate laparotomy wound as described above. Testes are put in the scrotum irrespective of whether they are normal or ischemic. Only frankly necrotic gonads may be removed. Postoperatively, if resection and anastomosis are carried out, nasogastric aspiration and intravenous fluids are continued in the infant until peristalsis returns and feeds are established. Antibiotics are continued for 5 days. The complications are as discussed above.

Short bowel syndrome and surgical techniques for the baby with short intestines

MICHAEL E. HÖLLWARTH

INTRODUCTION

The term *short bowel syndrome* (SBS) is defined by most authors as a state of significant maldigestion and malabsorption requiring prolonged parenteral nutrition. SBS was defined in term neonates by Rickham[1] in 1967, as an extensive resection of all but a maximum of 75 cm of the small gut. This corresponds to 30% of the total jejunoileal length in term newborns. SBS in a premature newborn corresponds, according to Touloukian, to 30% of the calculated intestinal length for the given gestational age (GA), too.[2] A more recent publication measuring bowel length *in vivo* shows that it is about 100 cm at GA of 27–29 weeks, 157 cm at 39–40 weeks, and 239 cm between 1 and 6 months.[3] The term *intestinal failure* (IF) is often used for a larger group of patients with a variety of diseases and the inability to sustain an adequate homeostasis and growth by normal enteral nutrition.[4]

Around 80% of SBS cases occur in the neonatal age group. The causes can be subdivided into prenatally acquired diseases (gastroschisis, multiple atresia, Hirschsprung disease; 17%); postnatally catastrophic events leading to a subtotal loss of small bowel, such as necrotizing enterocolitis (36%) or volvulus (19%); and other rare causes or trauma (7%). The prevalence of SBS has increased over the last decades due to the progress in intensive care medicine, allowing more babies to survive extensive loss of small bowel. A recent Italian study showed an incidence of 0.1% in all live births and 0.5% among intensive care unit (ICU) admissions.[5]

In the past, extensive loss of small bowel in newborns and babies used to be a catastrophic event nearly always followed by malnutrition and death. Reviewing the literature in 1965, Kuffer[6] found only nine surviving children with SBS. In 1972, Wilmore[7] reviewed 50 babies younger than 2 months with SBS and found that survival was possible with a 15 cm jejunoileum with the ileocecal valve, or with 38 cm jejunoileum without the ileocecal valve. In 1985, Dorney and colleagues[8] reported that long-term nutritional support today allows survival in infants with as little as 11 cm of jejunoileum with the ileocecal valve (5% of the total), or with 25 cm of jejunoileum without the ileocecal valve (10% of the total).

Intestinal adaptation is the term that characterizes the pathophysiology that follows intensive intestinal resection, and by which more than 80% of the babies with SBS do finally reach a normal life with entirely oral nutrition.[9] Adaptation is characterized by an early increase of blood flow to the intestinal remnants[10] and by long-term stimulation of intestinal, growth which enormously enlarges the absorptive surface area.[11] The latter includes an increase of villus height, crypt depth, intestinal length, intestinal thickness, and intestinal diameter. Recent experimental studies showed that angiotensin-converting enzyme has an important function regarding the apoptosis and proliferation of enterocytes after small bowel resection.[12] Water and solute absorption is enhanced in the colon, and colonic bacteria ferment undigested carbohydrates and proteins into short-chain fatty acids, which act as important energy providers and, apparently, as additional promoters of adaptation.[13,14]

The precise mechanisms of adaptation are not clear, but intraluminal nutrients and endogenous intestinal secretions stimulate growth.[15–18] Recently, it has been shown that ω-3 fatty acids from fish oil have a beneficial effect on liver function and ameliorate parenteral nutrition–associated liver disease.[19] In general, the higher the workload required for digestion and absorption, the more potent the stimulus for adaptation. In response to the nutrients and secretions, a large number of trophic polypeptides and other mediators are secreted. Over the years, some of them have attracted attention regarding their possible clinical value in promoting adaptation in SBS patients. First, gastrin was demonstrated to exhibit trophic effects on the small

bowel.[20] Gastric secretions and acid production, as well as serum gastrin levels, are initially elevated in patients with SBS. Enteroglucagon is another hormone that has been shown to stimulate the adaptive response *in* the intestinal tract in animal experiments and humans.[21] Since monoclonal antibodies failed to block this trophic effect, recently, precursors of enteroglucagon are considered to be responsible for the intestinal effects. Glucagon-like peptide-2 is a trophic hormone that has an important role in controlling intestinaladaptation.[22,23] Human growth hormone (GH) in combination with epidermal growth factor, or with insulin-like growth factor-1(IGF-I), has also been shown to regulate small intestinal growth and adaptation[24–27] IGF-I receptors have *been* identified in all segments of the gastrointestinal tract, and IGF-I stimulates DNA and RNA synthesis and cellular amino acid uptake.[28] The endogenous GH–IGF-I system is an important regulator of small intestinal growth and adaptation.[29] A number of other growth factors are widely discussed in the literature.[9]

Among the amino acids, glutamine (GL) plays an important role in the maintenance of intestinal structure and function by providing the energy required by cells with a rapid turnover, such as macrophages and enterocytes. Patients after major trauma or in chronic catabolic states benefit from GL supplementation.[30] In addition, enteral nutrition with GL has been shown to have an effect on glucose and sodium absorption in animals.[31] Ziegler et al. have shown that GH increases GL uptake after intestinal resection, supporting the evidence that GL exerts trophic effects in the small intestine and the colon of patients with SBS.[32] More research, however, is needed, since studies on GL are controversial.[25,33] Prostaglandin (Pg) E2 and polyamines have also been shown to stimulate cell proliferation in animal experiments by increasing blood flow and DNA synthesis.[34,35] Experimental evidence exists that testosterone enhances adaptation after small bowel resection in cats.[36] Recently, it has been shown that dietary supplementation with *v*itamin D stimulated cell proliferation and decreased cell apoptosis in a rat model of SBS.[37]

Within 1 year in more than 80% of the patients, adequate intestinal adaptation occurs, and they can be weaned off parenteral nutritional support. However, this process can cause significant embarrassment and psychological stress to the child and his/her family, as well as complications such as septicemia, cholecystitis, and chronic liver fibrosis. Therefore, the ability to reliably predict the potential of a patient to be weaned from parenteral nutrition gained significant attention. Citrulline is a free amino acid in plasma and is produced by the metabolism of GL and proline in small bowel enterocytes. It has been shown that plasma estimations of citrulline correlate well with the bowel length in children and adults, and can be used as predictors of whether weaning from parenteral nutrition will be possible or not.[38,39] The cutoff point distinguishing children who reach independence of parenteral nutrition seems to be 15 μmol/L.[40,41] Citrulline is also a potent marker of rejection after intestinal transplantation (TPX) as well as in children with graft-versus-host disease.[42]

While intestinal TPX has still limited clinical applicability with long-term survivors, ongoing interest exists in surgical methods to enhance nutrient absorption. This chapter reviews current surgical techniques for patients with SBS, with special emphasis on their clinical applicability.

SURGICAL TACTICS IN SITUATIONS REQUIRING EXTENSIVE INTESTINAL RESECTION

Malformations such as multiple intestinal atresias or gastroschisis with atresia can cause a congenital SBS in the newborn. Acquired conditions such as intestinal strangulation by midgut volvulus or necrotizing enterocolitis may require extensive intestinal resection. For patients at risk of SBS, surgery must be adapted to preserve as much small bowel as possible.

In intestinal atresias, dilated intestinal loops should be preserved instead of resected in the usual way. In volvulus, second-look procedures can help the surgeon decide which parts of the intestine are definitely lost. In extensive necrotizing enterocolitis, intestinal loops of questionable viability should be decompressed by an enterostomy, not resected. The ileum is more important than the jejunum, since it is the site of vitamin B_{12} and bile acid absorption. Also, the ileum has a much greater capacity for intestinal adaptation. When resection has been completed, the remaining jejunum and ileum should be measured from the ligament of Treitz all the way down to the ileocecal valve, with a thread laid along the antimesenteric border. Intestinal loops shrink considerably during manipulations, and the real intestinal length is difficult to measure *in vivo*. This may be one reason that survival does not seem strictly related to the length of the remaining bowel.

SURGICAL TECHNIQUES IN SBS PATIENTS

General agreement exists that the therapeutic priorities in patients with SBS consist of the stabilization of the patients' conditions, the evaluation of the adaptive capacities of the intestinal remnants, and the clarification of the patients' special needs. Therefore, the primary surgical aim is restoration of the bowel continuity as soon as possible in order to allow all remaining intestinal segments to take part in the adaptation process. Additional surgical strategies come into play only if

1. The absorptive area is definitely too small to allow enteral feeding
2. Dysmotility in grossly dilated loops entails stagnation of chyme
3. Intestinal transit is too fast to allow sufficient absorption of nutrients (Table 73.1)

Intestinal TPX is, of course, the most effective method to increase intestinal absorptive area immediately. Indications

Table 73.1 Surgical strategies in SBS patients

To increase passage time	To increase absorptive surface area	To improve peristalsis
Antiperistaltic segment	Serosa patching	Tapering
Colon interposition	Mucosa transplantation	Tapering and lengthening
Intestinal valves	Small bowel TPX	
Artificial invagination		

for TPX are patients after a catastrophic abdominal event with little or no small bowel remaining, and patients with SBS and irreversible liver failure due to progressive total parenteral nutrition (TPN)–associated hepatic dysfunction. Until recently, the results of intestinal TPX had been poor, mainly due to a high rejection rate. With the introduction of new immunosuppressive drugs, such as tacrolimus and OKT3 in addition to steroids, significant progress has been achieved with a 1-year transplant survival rate approaching 75% in recent series. However, 10-year results after intestinal TPX show a patient survival of around 43% and a graft survival of 23%, suggesting that a good functioning home parenteral nutrition (HPN) offers, in general, a better long-term outcome avoiding the adverse effects of immunosuppression, including lymphoproliferative diseases related to Epstein–Barr virus (EBV) infections.[43–46]

Therefore, current surgical procedures usually support only one or two of the aforementioned factors. The predominant problem in a given patient has to be evaluated carefully to choose the method most likely to enhance the absorptive capacity of the intestinal remnants. General agreement exists that most of such techniques are not indicated as a primary procedure. The priorities are as follows: (1) stabilization of the patient's condition, (2) evaluation of the adaptive capacity of the intestinal remnants, and (3) clarification of the patient's special needs.

INEFFICIENT PERISTALSIS

Tapering

In a newborn with multiple intestinal atresias resulting in SBS, bowel that is congenitally enlarged due to chronic obstruction should be preserved. However, the low contraction pressure in such bowel segments results in inefficient to-and-fro peristalsis, easily demonstrated by radiological studies. Inefficient peristalsis can lead to stasis of the chyme, symptoms of obstruction, and a contaminated bowel syndrome caused by bacterial overgrowth. Tapering of dilated loops can be accomplished by a triangular resection of an antimesenteric segment (Figure 73.1). The disadvantage of this type of tapering is that it reduces the available intestinal surface area. Thus, the technique can be recommended only for patients with sufficient intestinal length and absorptive area in whom inadequate peristalsis is the main problem.

Tapering can also be accomplished simply by turning in the redundant tissue (Figure 73.1). This technique avoids reduction of intestinal surface area and results in normal bowel function.[47,48] Whichever method is used, effective and propulsive peristalsis takes at least 3 weeks to return.

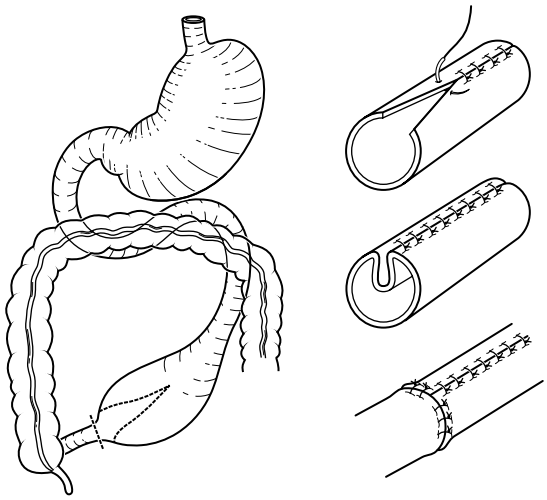

Figure 73.1 Tapering can be performed either by resection of a triangular antimesenteric segment or by turning in the redundant tissue. The latter method saves all the available resorptive surface area.

Tapering and lengthening

In 1980, Bianchi[49] reported an experimental procedure combining the tapering of dilated loops with use of the redundant tissue for lengthening the bowel. Anatomically, the mesenteric vessels from the last parallel arcade divide into anterior and posterior branches entering the bowel from either side of the midline. Especially in dilated segments, a relatively broad avascular plane in the midline can be used to separate the vascular layers. Longitudinal division of the bowel can be accomplished this way, while preserving sufficient nutrient vessels to either half of the intestine. Longitudinal closure of each intestinal segment and isoperistaltic end-to-end anastomosis doubles the intestinal length of this segment.

Bianchi[50] in his experimental reports and Boeckmann and Traylor[51] in the first clinical report used a Gastro-Intestinal-Anastomosis (GIA) stapler to divide the intestinal parts. Although the procedure using the GIA stapler is fast, it produces two rigid intestinal segments and consumes absorptive surface area. Aigrain et al.[52] recommend division with scissors and a manually sutured anastomosis. Seromuscular stitches guarantee a maximum of preserved mucosa (Figure 73.2a). Since both sections of the bowel hang on the same mesenteric segment, a helix-like

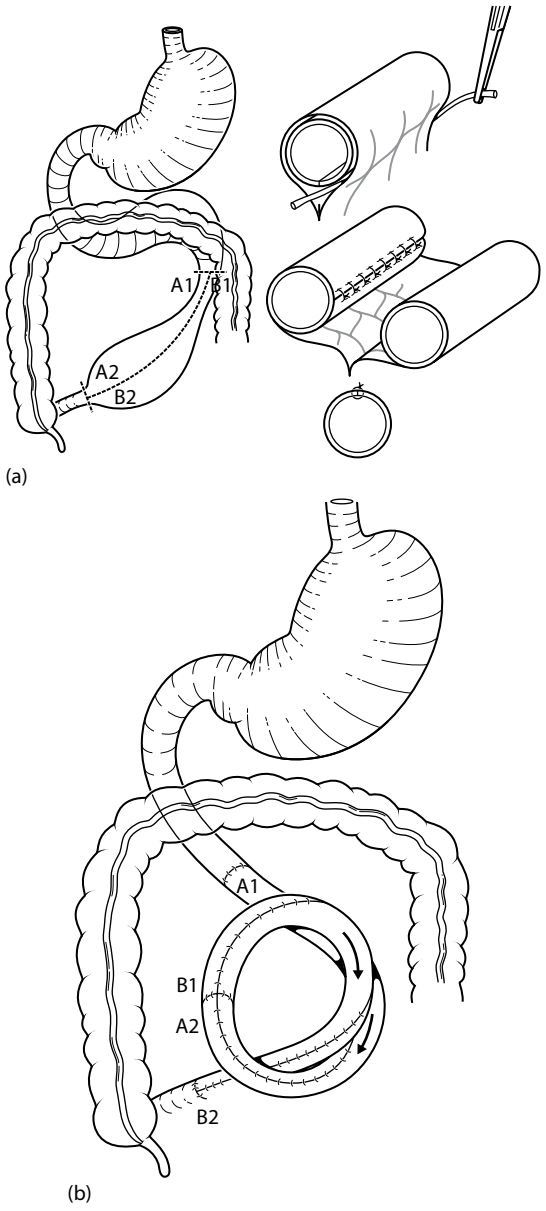

Figure 73.2 **(a)** Bianchi's tapering and lengthening is critical for the intestinal circulation. A Penrose drain facilitates the division of the segments. Seromuscular stitches save as much mucosal surface area as possible. **(b)** The helix-like arrangement of the two separated parts allows the anastomoses to be performed with minimal traction on the vessels.

isoperistaltic anastomosis is easier to perform than an anastomosis with the two segments sliding one on the other. The helix technique avoids traction on the nutrient vessels, which is critical because necrosis of the divided segments has been reported (Figure 73.2b).[53] Experimental studies in dogs showed that intestinal tapering and lengthening may impair nutritional status as well as intestinal adaptation and absorption.[54]

Bianchi's method has been used in more than 50 infants. Necrosis of half of the segments occurred in only one baby.[55] In some of these infants, the primary length of the intestinal segments was as long as 40–80 cm, which would call into question the indication of some of these procedures. According to Bianchi's[55] own experience, the method has proved successful when performed not in the newborn or early phase of a short bowel problem but in a later stage of the disease, on so-called self-selected survivors, i.e., patients in stable general conditions and free of severe complications, such as liver failure. This statement can be confirmed by the author's experience with two SBS newborn babies with 15 cm and 20 cm small bowel remnants, no ileocecal valve, and 40% of the normal colonic length. Although Bianchi's procedure was performed completely uneventfully and nearly doubled the intestinal length, both babies suffered from a poor peristalsis and died at the age of 1 year with progressive liver failure. Thus, patients with inherent motility disorders may not be selected for this procedure.[56]

Another method of bowel tapering and elongation has been published by Kimura and Soper.[57] This procedure consists of an initial coaptation of the small bowel remnant to a host organ (liver, abdominal wall), and after collaterals have been developed, a secondary longitudinal split of the bowel is done to provide two loops, one from its antimesenteric half and the other from its mesenteric half. This procedure has been successfully used in two infants.[57,58]

A recently published procedure that can be used in cases with insufficient peristalsis due to dilated intestinal loops and also as a lengthening procedure is the so-called STEP—serial transverse enteroplasty.[59,60] The refashioning of dilated intestinal loops is achieved by serial alternating and opposite transections of one-third or half of the intestinal lumen creating a zigzag-like figure (Figure 73.3). The method has the advantage that it is technically much easier than Bianchi's procedure and the achieved lengthening is significantly longer. Long-term results show that a majority of children can be weaned off parenteral nutrition except children with motility problems.[61–63]

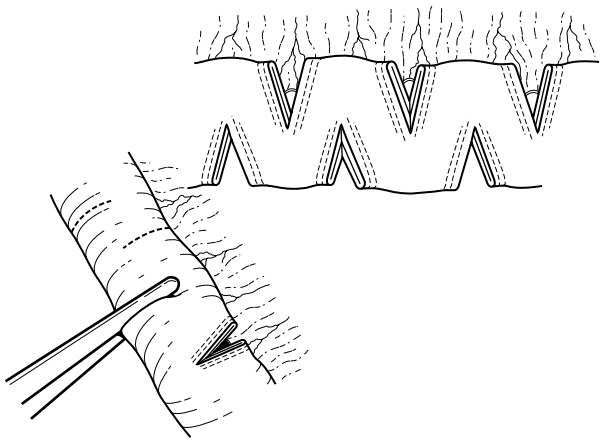

Figure 73.3 Serial transverse enteroplasty (STEP) consists of semicircular alternating incisions with the GIA stapler resulting in a zigzag-like elongation of the small bowel.

INADEQUATE INTESTINAL TRANSIT TIME

For a long time, the ileocecal valve was supposed to prolong intestinal transit time. A review from Dorney et al.[8] showed that the presence of an intact ileocecal valve is crucial to survival of newborns after extensive loss of small bowel. These findings have been confirmed by the author's experience: all babies with SBS and a preserved ileocecal valve survived, while all patients with fatal outcome did not have the valve.[64] In contrast, Coran et al.[65] and Kaufmann et al.[66] have not shown a difference in outcome of SBS patients with regard to the presence or absence of the valve. Furthermore, experimental evidence exists, that bacterial translocation in SBS rats without an ileocecal valve is significantly lower when compared with animals with a preserved ileocecal valve.[67,68] While definite evidence of a beneficial role of the ileocecal valve in SBS patients is lacking, nevertheless, the valve should be preserved whenever possible, and it probably plays a role with regard to the prolongation of the intestinal transit time.

Antiperistaltic small intestinal segment

Reversal of distal small bowel loops has been studied experimentally for years. Since the original report by Gibson and colleagues[69] of the use of reversal of small intestine in an adult, this has been, in the past, the most commonly used method for patients with SBS (Figure 73.4). The antiperistaltic small bowel segment acts as a physiological valve by causing retrograde peristalsis; therefore, it should always be located at the end of the intestinal remnants. The ideal length of the reversed segment appears to be 10 cm in adults and 3 cm in infants. In a 3-month-old patient in the author's department, a 3 cm antiperistaltic segment (out of a total of 11 cm small bowel) was helpful for intestinal adaptation. At 4 years of age, when the child was nourished completely orally, the total radiological small bowel length had reached 1 m, with a swinging of the opaque meal at the probable location of the antiperistaltic segment.[70] The patient is today 38 years old and needs only regular supplementation of fat-soluble vitamins (A, D, E, K). A more recent report on 38 adult patients permanently depending on parenteral nutrition showed that nearly half of them could be weaned by reversal of a small bowel segment, with significant gain in absorptive bowel function.[71]

Colonic interposition

Isoperistaltic or antiperistaltic interposition of the colon has the advantage of using none of the small intestinal remnants. The method was developed by Hutcher et al.[72,73]

The isoperistaltic segment should thus be interposed proximally either between the jejunum and ileum if the jejunal segment is short and the ileal segment long, or between the duodenum and jejunum if the latter is long and the ileum short (Figure 73.5). Isoperistaltic colonic interposition slows down the rate at which nutrients are delivered to the distal intestine by slowing peristaltic activity.[74] The optimal length of an interposed colon has not been defined. Glick et al.[75] used 10–15 cm long segments in small babies, while Garcia and colleagues[76] used a 24 cm segment in a 14-month-old infant.

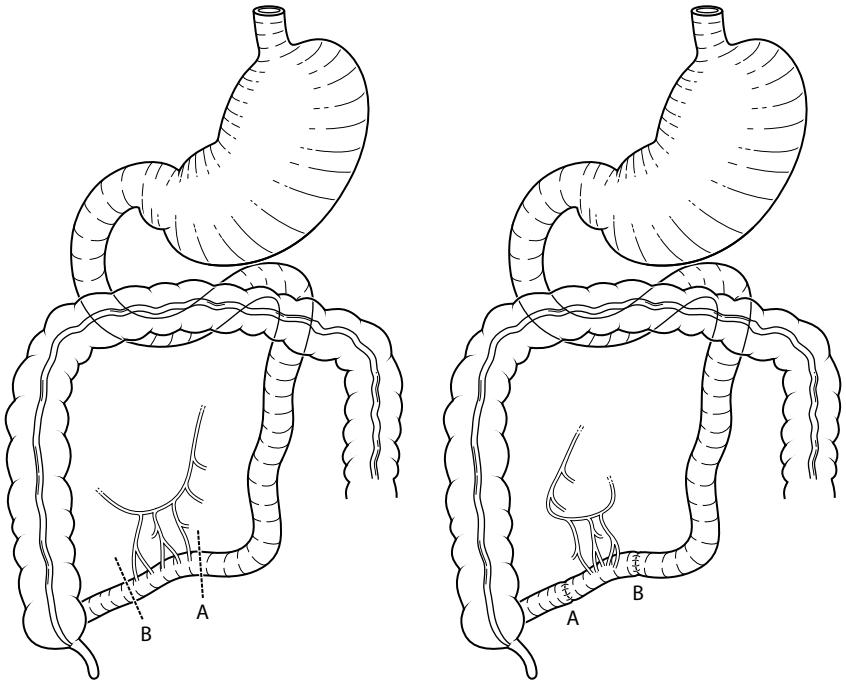

Figure 73.4 The antiperistaltic intestinal segment should be interposed close to the ileocecal valve or at the end of the small bowel. The optimal length in newborns is around 3.0 cm.

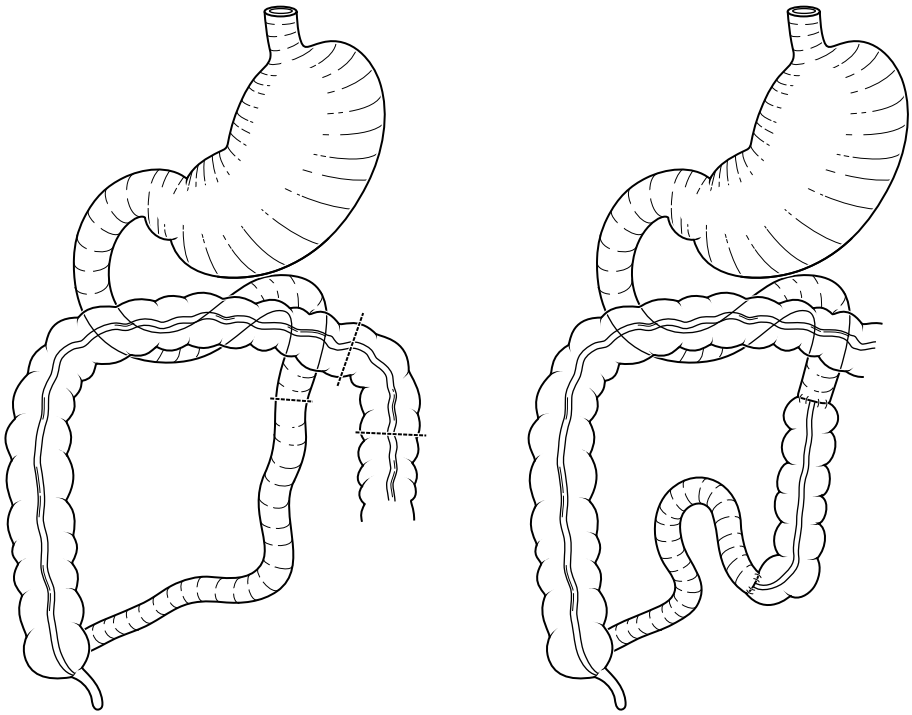

Figure 73.5 The isoperistaltic colonic interposition should be interposed proximally (while the reversed colonic interposition should be used distally). The length of an isoperistaltic interposition recommended is within 10–20 cm.

Besides the beneficial effect of slowing peristaltic activity, the interposed colonic segment increases the bowel length between the duodenum and cecum. Furthermore, colonic loops adapt to the function of the small bowel and can absorb water, electrolytes, and nutrients by active transport mechanism.[77] Experimental studies in rats have shown a significant increase in crypt depth, mucosal thickness and maltase concentration of the interposed segment.[78]

Reported clinical results show that out of seven infants with isoperistaltic interposition, four survived.[75,76] In two, the length of the intestinal remnants was not reported; in the other two, they were 39 and 63 cm. An adult patient with 5 cm of jejunum and 7 cm of ileum after a midgut volvulus could be weaned from parenteral nutrition completely after interposition of an 18-cm-long isoperistaltic colon. Recent experience in our department with proximal isoperistaltic colonic interposition and an additional distal STEP procedure in newborns with very short bowel, e.g., after gastroschisis with intrauterine volvulus and vanishing bowel, seems to be very promising.

Intestinal valves and pouches

As mentioned earlier, while the benefits of the ileocecal junction on long-term outcome of babies with SBS has been questioned, there exists a large body of evidence as to its powerful impact on intestinal transit time by slowing the passage of intraluminal nutrients into the colon. Therefore, a variety of experimental surgical procedures have been devised to slow down the intestinal transit time by creation of artificial valves.[79,80] Constriction of the bowel by sutures and artificial sphincters,[75] mechanical or chemical denervation of segments,[81] and intussusception techniques has been studied extensively.[82,83] Clinical experience with intussuscepted valves is very limited. Waddell et al.[84] performed a reversed intussusception of the colon into the jejunum in three adults, one of whom subsequently developed an obstruction. Ricotta et al.[82] constructed a 4-cm-long nipple-like ileocecal valve (Figure 73.6) in a 15-year-old boy, which appeared to be helpful.

RESULTS

Despite the variety of surgical techniques designed to support intestinal adaptation after extensive loss of small bowel, none can be recommended unequivocally. In the past, the overwhelming majority of babies with SBS had been treated exclusively by parenteral nutritional support until intestinal adaptation allowed entirely oral nutrition. Full enteral feeding has ultimately been attained in infants with originally as little as 15 cm of the small bowel with the ileocecal valve preserved, or 25 cm of jejunoileum when it was missing.[85] Survival rates of 75%–83% are being reached in newborns, and 100% in children at or above 2 years of age.[86,87] The survival rate of surgically treated newborns with SBS born after 1985 was 96% in Goulet's clinic.[88] Survival rate of very-low-birth-weight (VLBW) infants with SBS enrolled in a national registry between 2002 and 2005 was 98% after 60 days and 79% after 180 days.[89] A further study showed that 27 out of 28 children with a bowel remnant <20 cm survived, and 48% of them have been weaned from parenteral nutrition. The successfully

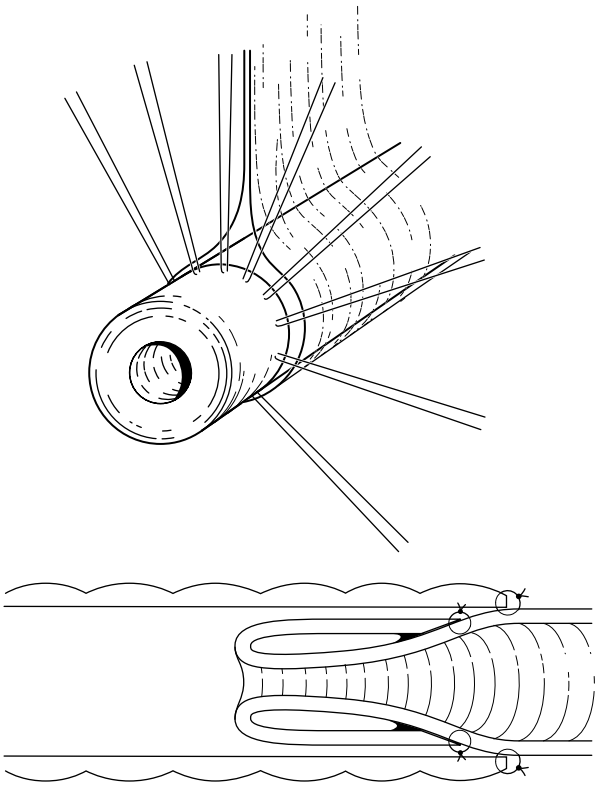

Figure 73.6 Nipple-like ileocecal valve according to Ricotta. The optimal length in newborns is not defined but will be around 1–2 cm. In a 15-year-old boy, a 4-cm-long valve worked well. Seromuscular stitches allow the precise adaptation of the mucosal layers.

rehabilitated patients were more likely to have an intact colon with the ileocecal valve.[90]

CONCLUSION

In conclusion, surgery is indicated only in selected patients either to achieve effective propulsive peristalsis or to prolong intestinal transit time. However, adjunctive surgical procedures should be postponed until the special needs of individual patients are evident. Approximately 10% will benefit from surgical interventions, either by prolongation of transit time or by remodeling parts of the intestine. Patients with total loss of small bowel or progressive liver failure may benefit from the progress made by intestinal TPX, although 5-year survival rate does not lie much above 50%.[43]

Megacystis microcolon intestinal hypoperistalsis syndrome

PREM PURI AND JAN-HENDRIK GOSEMANN

INTRODUCTION

Megacystis microcolon intestinal hypoperistalsis syndrome (MMIHS) is a rare congenital and generally fatal cause of functional intestinal obstruction in the newborn. The main characteristics for this syndrome are abdominal distension caused by a massive enlarged nonobstructed urinary bladder, microcolon, and decreased or absent intestinal peristalsis.[1] MMIHS is usually associated with incomplete intestinal rotation and shortened small bowel.

PATHOGENESIS

MMIHS was first described by Berdon et al.[1] in 1976. To date, over 220 cases have been reported in the literature.[2] Although several hypotheses have been proposed to explain the pathogenetic background of MMIHS (neurogenic, myogenic, and hormonal), the etiology of this syndrome remains unclear.

In the majority of MMIHS patients, histologic studies of the myenteric and submucosal plexuses of the bowel revealed normal ganglion cells. However, in some patients, decreased amounts of ganglion cells or hyperganglionosis together with giant ganglia were found.[3,4] In 1983, Puri et al.[5] showed vacuolar degenerative changes in the smooth muscle cells (SMCs) with abundant connective tissue between muscle cells in bowel and bladder of patients with MMIHS. This leads to the suggestion that a degenerative disease of SMCs could be the cause of this syndrome. Several subsequent reports have confirmed evidence of intestinal myopathy in MMIHS.[6–8]

More recently, Piotrowska et al.[7,9] reported absence of interstitial cells of Cajal (ICCs) in bowel and urinary bladder of patients with MMIHS. ICCs are pacemaker cells, which facilitate active propagation of electrical events and neurotransmission. Their absence may result in hypoperistalsis and voiding dysfunction in MMIHS.

Furthermore, absence or marked reduction in α-smooth muscle actin and other contractile as well as cytoskeletal proteins in the smooth muscle layers of MMIHS bowel have been reported.[7,8] Contractile and cytoskeletal proteins are important structural and functional components of SMCs and play a vital role in the interaction of filaments in smooth muscle contraction.

Rolle and Puri[10] showed pathological changes within the bladder SMCs and markedly increased collagen deposits within the bladder wall of MMIHS patients, and therefore concluded that the detrusor muscle is strikingly abnormal and this is the likely cause of voiding dysfunction in the affected patients.

Other studies support the hypothesis that the absence of a functional α3 subunit of the neuronal nicotinic acetylcholine receptor (ηAChR) may be responsible for the predominant intestinal manifestation of smooth muscle myopathy, leading to manifestation of MMIHS.[11–13] This lack of functional α3 and the absence of smooth muscle actin in the circular layer of small bowel muscularis were recently suggested to be associated with a de novo deletion of the proximal long arm of chromosome 15 (15q11.2).[14]

The evaluation of the genetic background of MMIHS resulted in a number of recent publications that suggest the enteric smooth muscle actin gamma 2 (ACTG2) as the first gene to be clearly associated with MMIHS[15–17] and intestinal pseudo-obstruction. Some authors suggest to reorganize the clinical entities of MMIHS, prune belly syndrome, hollow visceral myopathy, and intestinal pseudo-obstruction into a spectrum of ACTG2-related disorders.[15] The identification of a possible genetic background might have a relevant impact on prenatal counselling in the future.

The occurrence of MMIHS in 15 sets of affected siblings (Table 74.1) and four further index patients with a confirmed diagnosis and a probably affected sibling as well as consanguinity in four of the confirmed sibling sets suggest an autosomal recessive pattern of inheritance.[20,26,36]

PRENATAL DIAGNOSIS

A total of 182 cases of MMIHS reported in the literature were reviewed by Puri and Shinkai.[37] The most frequent finding reported on fetal sonography (n = 54) associated with MMIHS was enlarged bladder (88%) together with hydronephrosis (57%). In 59% of the fetuses, normal amniotic fluid volume was detected, whereas 33% revealed increased volume and 7% had decreased volume. Only 5% showed abdominal distension caused by dilated stomach. Three cases (5%) of oligohydramnios during the second and early third trimester were reported, which may probably be related to the functional bladder obstruction (Table 74.2).

Enlarged bladder, detectable from 16 weeks of gestational age, was shown to be the earliest finding in MMIHS in serial obstetrical ultrasonography (Figure 74.1). A later finding was hydronephrosis, caused by the functional obstruction of the bladder. Usually polyhydramnios develops late, appearing during the third trimester.

Recent reports have described prenatal magnetic resonance imaging (MRI) in patients with suspected genitourinary and gastrointestinal tract abnormalities following ultrasound examination.[38–40] In contrast to sonography, MRI not only demonstrated urologic abnormalities but also identified early stages of gastrointestinal pathology. Hence, the authors advocate MRI as an ancillary imaging technique whenever routine ultrasonography screening demonstrates genitourinary pathology with a need for further investigation.

Table 74.2 Prenatal ultrasound findings

Ultrasound findings	%
Enlarged bladder	88
Hydronephrosis	57
Normal amniotic fluid volume	59
Increased amniotic fluid volume	33
Decreased amniotic fluid volume	7
Dilated stomach	5

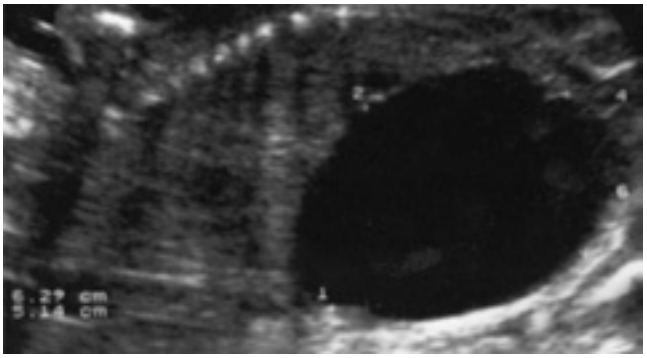

Figure 74.1 Massive enlarged fetal bladder, longitudinal view of abdominal ultrasound at 22 weeks gestation, fetus in prone position.

CLINICAL PRESENTATION

Review of the current literature revealed a female-to-male ratio of 2.4:1.[2] With regard to the duration of pregnancy, 59% of the reported patients were born at term, 26% at 36–39 weeks of gestation, 12% at 32–35 weeks, and 3% at 31 weeks or less. Eight cases of dystocis delivery due to abdominal distention were reported, and caesarean section was required in four cases.[37] Nine terminations of pregnancy after the detection of MMIHS via ultrasound have been reported.[2]

In four cases, paracentesis was needed because the bladder was so distended that the baby could only be delivered vaginally after removal of 250, 500, 650, and 500 mL of urine, respectively, from fetal bladder. The mean birth weight was found normal (3000 g) for gestational age.[37]

Clinical symptoms of MMIHS are similar to other neonatal intestinal obstructions. Abdominal distension is a constant and early finding. It is a consequence of the enlarged, unobstructed urinary bladder with or without upper urinary tract dilatation. The majority of patients were not able to void spontaneously. However, a distended, nonobstructed urinary bladder could be easily relieved by catheterization.

Of 182 infants, 61 had bilious vomiting and 23 failed to pass meconium. Other symptoms included bile-stained vomiting and absent or decreased bowel sounds.[37]

RADIOLOGICAL FINDINGS

Radiological evaluation usually suggests the diagnosis of MMIHS. Plain abdominal films showed either dilated small bowel loops or a gasless abdomen with evident gastric bubble in the vast majority of 182 reviewed cases.[37] An enlarged urinary bladder was present in all patients who had cystography or ultrasonography (Figure 74.2). Vesicoureteral reflux was found in 8 patients, and in 84 patients, intravenous urography or ultrasonography detected unilateral or bilateral hydronephrosis.[3,18,37,41–43]

Barium enema showed microcolon in all 71 patients in whom this study was performed, and in 39 cases, malrotation was associated (Figure 74.3).

In patients who underwent an upper gastrointestinal series, both before and after laparotomy constantly revealed hypo- or aperistalsis in stomach, duodenum, and small bowel. Reverse peristalsis from small bowel into the stomach was observed in three cases; in two cases, hypoperistalsis was associated with gastroesophageal reflux; and in one case, the esophagus was aperistaltic.[37]

SURGICAL OR AUTOPSY FINDINGS

Surgical findings and management vary throughout the publications, and exact surgical procedures are reported inconsistently.

The most frequently reported findings at surgery or autopsy are megacystis and microcolon and are present in all patients (Figure 74.4). Furthermore, malrotation, short bowel, and functional obstruction are frequently reported.[2] Approximately 70% of the reported patients, to date, underwent one or more surgical procedure.[37] Surgeons frequently performed gastrostomy, jejunostomy, ileostomy, cecostomy, and vesicostomy, mainly to decompress the intestinal and vesical system. However, the majority of reports state that surgical interventions did not improve enteral food intake, intestinal pseudo-obstruction, or bladder function.

Due to the various, infrequent, and fragmentary reports on surgical interventions combined with clinical outcome, no conclusion or recommendation can be made from these data. The majority of authors agree that the decision for surgical interventions should be made carefully, individualized, and restricted to supportive interventions such as enterostomy and vesicostomy.[2]

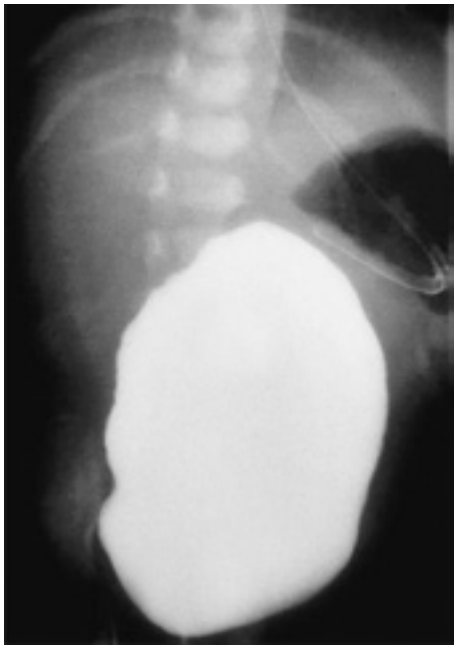

Figure 74.2 Voiding cystourethrogram showing massively enlarged bladder in an MMIHS patient.

Figure 74.4 Operative photograph of a massively dilated urinary bladder in MMIHS.

HISTOLOGICAL FINDINGS

Histologic studies of the myenteric and submucosus plexuses were reported in 93 out of 182 MMIHS cases.[37] Ganglion cells were normal in appearance and number in 72 (77%). In the remaining 21 cases (23%), various neuronal abnormalities included hypoganglionosis, hyperganglionosis, and immature ganglia.[4,37,44–50] The majority of reports do not mention histologic findings in the muscle layers of bowel and bladder wall. However, some authors found significant abnormalities in SMCs, such as thinning of the longitudinal muscle, seen in light microscopy.

Vacuolar degeneration in the center of the smooth muscle of bowel (11 cases) and bladder (8 cases) was shown in electron microscopy (Figure 74.5); furthermore, connective tissue proliferation was found in the bowel (9 cases) and bladder (8 cases). In three cases, the bladder showed elastosis. Electron microscopy revealed vacuolar degeneration of smooth cells in muscle layers of bowel and bladder in addition to neuronal abnormalities in two more patients.[37]

Other investigators have reported absence or marked reduction in α-smooth muscle actin and other contractile and cytoskeletal proteins in smooth muscle layers of MMIHS bowel.[7,8]

OUTCOME

Management of patients with MMIHS is frustrating. A number of prokinetic drugs and gastrointestinal hormones have been tried without success. Surgical manipulations of the gastrointestinal tract have generally been unsuccessful. The outcome of this condition remains fatal with a survival rate of approximately 20%. Although the survival rate increased in recent years, due to inconsistent reporting, the long-term survival of patients with MMIHS remains elusive. The oldest patients alive were reported to be 19 and 24 years at the time of publication.[2,51,52]

The most frequently reported cause of death in MMIHS patients was overwhelming sepsis followed by multiple organ failure and malnutrition. Furthermore, attempts to initiate sufficient enteral feeding have been reported to result in fatal pneumonia in several cases.[2,44,53,54]

The majority of MMIHS patients are maintained by parenteral nutrition, which predisposes for fatalities such as catheter sepsis and chronic liver failure.[53,55,56] Parenteral nutrition has been further associated with dyslipidemia and consequentially parenteral nutrition-associated liver disease (PNALD). One contribution to the observed increase in survival in recent years might have been the improvements of total parenteral nutrition (TPN) products. Especially the introduction of fish oil–based lipid emulsions has been reported to improve major lipid panels and resolve cholestasis in children with PNALD.[56]

Furthermore, early referral of affected patients to tertiary care may be a significant factor that may influence the survival of MMIHS patients, since early referral to specialized centers and multidisciplinary approach have been suggested to prevent the development of PNALD and increase survival in patients with intestinal failure.[57–59]

In a recent literature, 12 cases of multivisceral transplant surgery have been described with various outcomes.[2] A 3-year survival of 50% has been reported in a series by Loinaz et al.[53] The majority received liver, pancreas, small bowel, and colon transplants. All survivors were reported to tolerate enteral feedings and showed adequate gastric emptying. In contrast, bladder function did not improve and catheterization had to be continued after transplantation.[53]

Outcome of multivisceral transplant surgery might have been improved over the last years.[60,61] However, transplant patients still face major complications such as infection/sepsis, rejection, post-transplant lymphoproliferative disease, mechanical dysfunction, and vascular complications.[62]

The decision for surgical intervention should be made carefully, individualized, and, in most cases, restricted to supportive interventions (such as feeding enterostomy and decompressing ostomy), since most explorations have not been helpful and probably are not necessary.

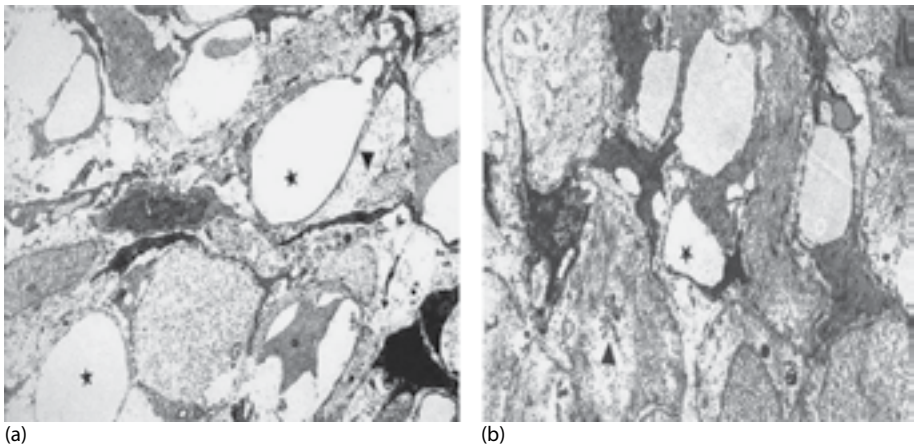

Figure 74.5 Electron microscopy: SMCs from ileum **(a)** and bladder **(b)** from a patient with MMIHS showing vacuolar degeneration (*) in the center of SMCs.

Future parenteral counselling will be based on continuously improving prenatal diagnostics and increasing knowledge on the pathogenesis of MMIHS. It is therefore crucial that the counselling physician educates the future parents to his or her best knowledge and up-to-date evidence to allow them to make a substantiated decision on the sequel of the pregnancy.

Biliary atresia

MARK DAVENPORT

INTRODUCTION

There is still much to learn about biliary atresia (BA), why it happens and how it happens being good examples of areas where there is too much speculation and not enough hard evidence. What is only too obvious is that if it is untreated, it progresses to end-stage cirrhosis and is potentially fatal within the first 12–18 months. A treatment strategy has evolved, which, in the best hands, will give a 90% chance of long-term survival for all infants born with the disease, but even in these survivors, there are still significant morbidity and problems to overcome. Nonetheless, it is compatible with normal life.

HISTORY

The first documented case of BA was reported in English in 1891 by John Thompson.[1] He was a physician in Edinburgh, and his newborn patient developed jaundice, passed only white-colored stool from an early age, and ultimately died of liver failure with ascites at about 6 months. Her postmortem showed a normally formed but empty gallbladder and absence of the common hepatic duct (CHD).

Further reports followed, but no real treatment could be offered until surgeons began to operate on some of these infants. The most significant series published was that by Ladd in 1928, who reported his experience in 10 cases of surgical jaundice—some of which were BA.[2] Fairly quickly afterward, it was realized that only a small proportion (having "correctable" BA) were suitable as surgical candidates, as at exploration, a patent part of the biliary tree could be found and an hepaticojejunostomy performed. The remainder, those with "uncorrectable" BA, had an entirely solid biliary tract, certainly nothing one could anastomose to.

An alternative operation for the latter group was advocated by Morio Kasai (1922–2008), a surgeon working in Sendai, Japan.[3] He showed that a higher, more radical dissection was needed and if you removed the entire extrahepatic biliary tract, even if it looked solid, still it would contain microscopic biliary ductules, which connect to the intrahepatic biliary tract. If enough of these were uncovered, then bile flow could be restored. The reconstruction advocated was termed a *portenterostomy* to reflect this higher level of anastomosis. Once again, this proved not to be the complete answer, with unpredictable results and a significant proportion that showed no effect whatsoever.

Indeed, such was the skepticism that its value was only really recognized in North America and Europe during the 1970s. Most post-Kasai adult series as a consequence are therefore Japanese,[4] with some rare exceptions.[5] The alternative, if yet more radical, treatment for a terminally damaged liver also appeared in the 1960s—*liver transplantation*. Tom Starzl's first, albeit unsuccessful, attempt at human liver transplant occurred in 1963 in Denver, Colorado, in a 3-year-old girl with end-stage liver disease due to BA.[6] During that period, the art of immunosuppression was in its infancy, and transplant programs shut down, having failed to come to terms with consequent inevitable cellular rejection. The key discovery and clinical use of an effective immunosuppressive agent, cyclosporine, occurred in the 1980s and allowed transplant programs to flourish once more. From the 1990s, in most of the developed world, and still today, the strategy for management has been an attempt to resuscitate the native liver with a Kasai portoenterostomy, and if that fails, transplantation.[7]

ETIOLOGICAL HETEROGENEITY

BA is not one disease, certainly not one with a single cause (Figure 75.1). It seems to be a phenotype resulting from a number of different etiologies. We can define perhaps four clinically distinct groups:

1. Isolated BA
2. Biliary atresia splenic malformation (BASM) syndrome[8,9]
3. Cystic BA[10]
4. Cytomegalovirus-associated (CMV-associated) BA[11]

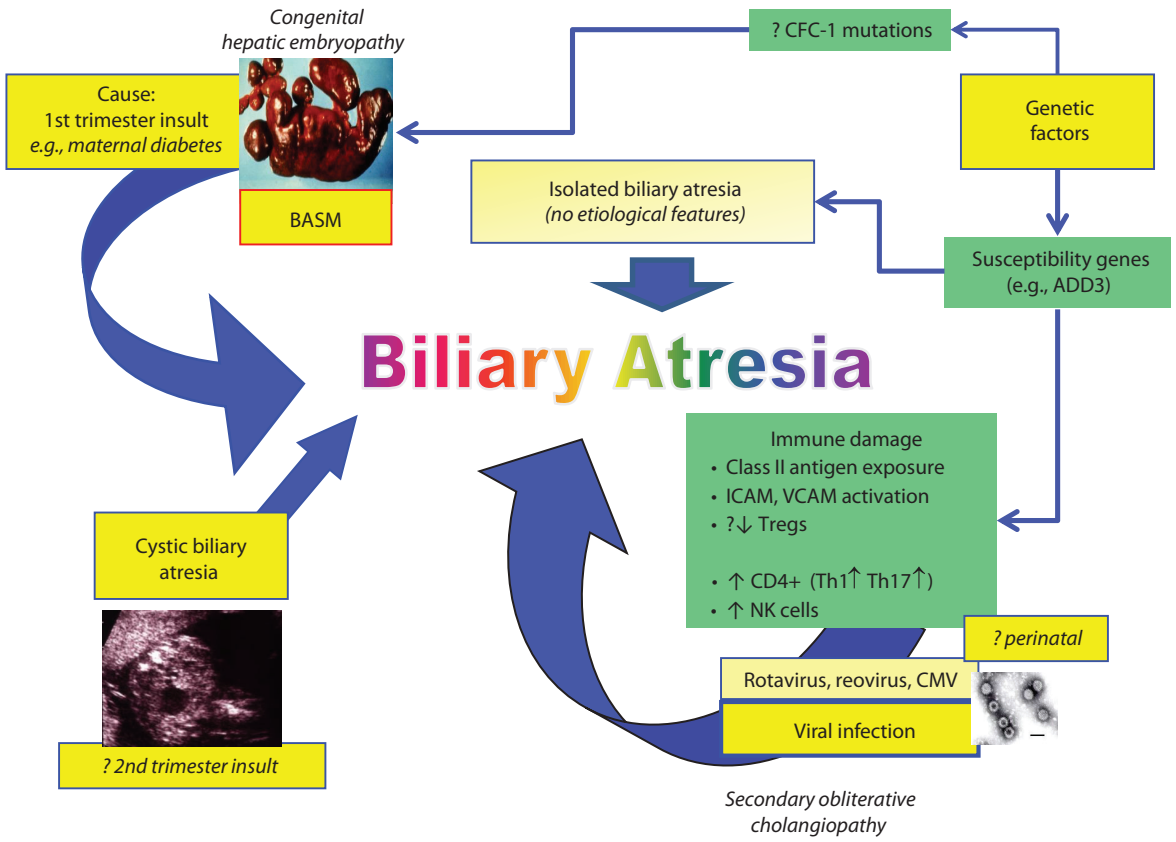

Figure 75.1 Schematic illustration of possible causes of biliary atresia: etiological heterogeneity. (Reproduced with permission from Davenport M, Biliary atresia: From Australia to the zebrafish, *J Pediatr Surg* 2016; 51:200–5.)

There are other relationships, although these are much rarer. Some cases appear to have an association with other gastrointestinal anomalies such as esophageal atresia and jejunal atresia (<2% of large series), and we have reported a small series with a defined chromosomal abnormality (e.g., cat-eye syndrome and chromosome 22 aneuploidy).[12]

We have now begun to use the term *developmental biliary atresia*[13] for those cases where there is almost unequivocal evidence for a prenatal onset and obstruction is evident by the time of birth. This would therefore include BASM (2) and cystic BA (3). By contrast, the onset of occlusion in CMV-associated BA (4) is probably perinatal with occlusion of a patent biliary system by virally mediated damage. Isolated BA (1) remains the most prevalent group, but it is more difficult to be certain of its actual etiology, because there aren't any real clues. Some of these could still be developmental in origin, and others, perinatal in timing.

BASM SYNDROME

We first reported what became known as BASM in 1993,[8] recognizing that splenic anomalies (not just polysplenia) were related in some way to BA and that there was also a peculiar but consistent association with cardiac defects, situs inversus, preduodenal portal vein, and absence of the vena cava (Table 75.1). The reasons for this are still obscure, but it has been suggested

Table 75.1 Spectrum of anomalies in biliary atresia splenic malformation syndrome

Organ system	Malformation
Splenic	Polysplenia, double spleen (95%) Asplenia (5%)
Situs determination	Inversus (50%)
Venous	• Preduodenal portal vein (40%) • Portosystemic shunt (<2%) Vena cava (absence) (50%)
Intestinal development	Malrotation (60%)
Cardiac	ASD, VSD, Fallot's tetralogy, etc. (~40%)
Liver	Normal, "mirror-image," or symmetrical in situs inversus
Biliary appearance	Solid and scanty gallbladder, may be absent. Gallbladder often a midline structure with solid, symmetrical proximal biliary ducts.
Pancreas	Annular (<5%)
Miscellaneous	Immotile cilia syndrome (Kartagener's syndrome) Sacral agenesis

that the common factor is simply an embryonic "insult" in a critical window of the developing viscera—perhaps at 30–35 days' gestation. Whether this affects single specific genes or an array of developmental genes or proteins is not known.

Furthermore, at this stage, the only biliary structure is the extrahepatic bile and emerging gallbladder. This appears at about day 20 as an outpouching from the distal foregut and develops into a funnel-shaped structure with a lumen and a gallbladder evident by day 45. It is lined by cholangiocytes derived from foregut endoderm, expressing transcription factors common to the pancreas and duodenum (e.g., *PDX-1*, *PROX-1*, *HNF-6*). The molecular mechanisms regulating this phase of biliary development are not well described in humans, but mice deficient in Pdx-119 or Hes1 (a Notch-dependent transcription factor), Hnf-6, Hnf-1β, or Foxf1 (a transcription factor target for Sonic Hedgehog signaling) can show altered development of the gallbladder with a normal common bile duct (CBD).[14]

The intrahepatic bile duct system develops later from around the seventh week of gestation. It is tempting, therefore, to speculate that the primary failure in BASM is that of the extrahepatic bile duct.

There are also genes that appear to be important in both bile duct development (e.g., *JAG1*, *HNF-6*[15]) and visceral and somatic symmetry (e.g., *INV*, *CFC-1*[16,17]), although most work has been done in the mouse and actual correlation with mutations in humans is not that good. A possible genetic link was reported by Davit-Spraul et al.,[18] who found an increased frequency of mutations in the *CFC-1* gene (on chromosome 2) in patients with BASM, compared to controls.

A further interesting observation is that there is a definite link between maternal diabetes and BASM, in the same way that this condition can cause transposition of the great vessels, double outlet right ventricle, and sacral agenesis (although these do not form part of the usual spectrum of BASM).[8,9]

Finally, a small number of infants with BASM have immotile cilia syndrome (also known as Kartagener's syndrome), and this provides an interesting speculation as to mechanism. Certainly, dysfunctional cilia could be incriminated in the determination of visceral situs during the early days of gestation—leaving it essentially to chance. But how cilial dysfunction interacts with the developing biliary tree is not known. Normally, only rats and squirrel monkeys have ciliated intrahepatic bile ducts, although there may be chemosensory cilia on cholangiocytes in humans.

The macroscopic appearance of the biliary tree and liver is also somewhat different in BASM compared to isolated BA, with frequent absence of the CBD and a miniscule gallbladder and small proximal remnant. The liver is also usually symmetrical, whatever the nature of the abdominal situs.

PATHOLOGY OF BA

This is best described as an *occlusive pan-ductular cholangiopathy* affecting both intrahepatic and extrahepatic bile ducts.

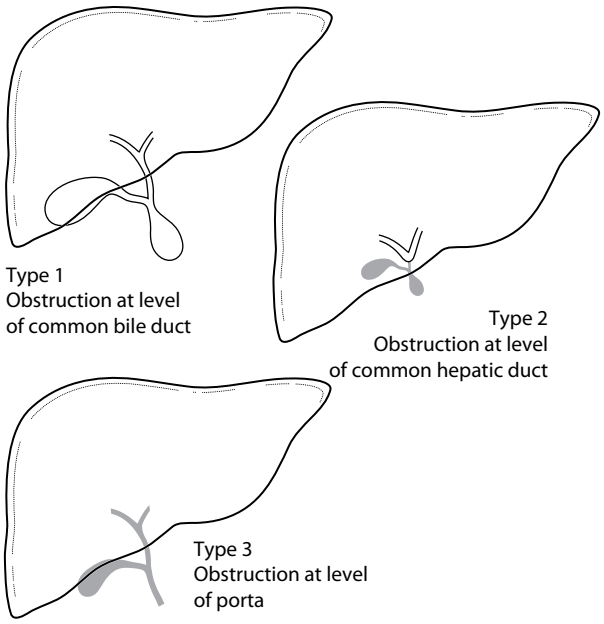

Figure 75.2 Classification of extrahepatic morphology in biliary atresia.

The commonest classification divides BA into three types based on the most proximal level of occlusion of the extrahepatic biliary tree (Figure 75.2). In types 1 and 2, there is a degree of preservation of structure in the intrahepatic bile ducts, but they are still irregular, deformed, and pruned—and do not dilate, even when obstructed. The commonest variant, type 3, occurs where there is typically a solid, dense fibroinflammatory proximal remnant at the porta hepatis. The distal duct may be atrophic, absent, or relatively well preserved—typically as a mucocele. Type 3 intrahepatic bile ducts are usually grossly abnormal with myriad small ductules coalescing at the porta hepatis. Sometimes this can be visualized radiographically as a "cloud."

Extrahepatic cyst formation may be evident and contain clear mucus or bile (depending on preservation with intrahepatic bile ductules). We prefer the name *cystic biliary atresia* for this entity, but the important thing is to distinguish it from simple obstruction in a cystic choledochal malformation.[10] The key to this is the cholangiogram, which will show a distorted, deformed nondilated intrahepatic duct system (if anything) in the former and a well-preserved and "treelike" dilated intrahepatic duct system in the latter. There should also be preservation of a decent epithelial lining in the latter on histology.

CELLULAR KINETICS AND INFLAMMATION IN BA

That BA is not simply a mechanical obstruction of the biliary tree has been obvious for some time now. There is a marked inflammatory process that is present in most types (possibly with the exception of BASM) as evidenced by an

obvious mononuclear infiltrate and expression of a variety of adhesion molecules on intrahepatic biliary and vascular epithelial surfaces.[19] Whether this is a primary or secondary phenomenon (to presence of bile outside biliary canaliculi, for instance) is arguable, but there is certainly evidence to support the former as a workable hypothesis.[19,20]

The infiltrate is largely composed of CD4+ T lymphocytes (specifically Th1 and Th17)[21,22] and CD56+ natural killer (NK) cells,[19,23] which exhibit markers for proliferation (CD71+) and activation (particularly LFA-1+ but also CD25+). There is a distinct subset of CD8+ cells, but many studies suggest that these may be less important and lack various markers of activation such as perforin, granzyme B, and Fas ligand.[24]

There is abnormal expression of cell adhesion molecules (proteins involved in cell–cell binding), with both ICAM-1 and VCAM-1 (but not e-selectin) being identifiable on epithelial structures in both the liver and, to a lesser extent, the biliary remnant.[19,25]

We also identified abnormally raised levels of the soluble adhesion molecules ICAM-1 and VCAM-1 in the circulation at the time of Kasai together with rising levels of these and inflammatory cytokines (e.g., IL-2, TNFα) postoperatively.[26,27] After about 6–9 months post-Kasai, these tended to come back down to more normal values (unpublished observation).

The resident (Kupffer cells) or recruited macrophages/monocytes appear to have a crucial role in the development of fibrosis seen in established BA. This may be as both the presenters of antigenic material in the first place and later as the initiating force for fibrosis in the development of chronic liver disease. Tracy et al.[28] in 1996 first showed increases in resident macrophages (CD68+) with marked expression of the lipopolysaccharide receptor, CD14+. Increased levels of both CD68+ cells and its circulating markers (TNFα and IL-18) have been shown impair to prognosis post-Kasai.[27,29]

VIRUSES AND BA

There have been a number of studies based on serology in infants with BA that initially suggested a causal link with perinatal viral infection (originally reovirus type 3[30]) but were later disputed.[31] However, actual viral footprints within the bile ducts have been much harder to demonstrate, and a causal link is still controversial.[32,33] Rauschenfels et al.[34] from Germany looked at wedge liver biopsies obtained from 74 infants at the time of Kasai portoenterostomy (KP) for a panel of DNA and RNA hepatotropic viruses. One or, indeed, more viruses were detected in about one-third of infants, and the detection rate increased with infant age. Rauschenfels et al. suggested that this showed that viral infection was a secondary finding and unlikely to be the specific cause of BA. Zani et al.[11] from our institution showed that there are clinically distinguishing features between infants who are CMV IgM positive (about 10% of overall series) and those who are CMV IgM negative. Infants with CMV IgM associated biliary atresia tended to come to surgery later, with worse (even if age-matched) liver biochemistry. Furthermore, histologically, the former group was characterized by a marked inflammatory infiltrate and increased fibrosis in their livers compared to the latter. The outcome following KP is also not as good as in infants with CMV IgM –ve BA (Figure 75.3). Other series, possibly where the prevalence of CMV is higher, have not shown such a marked difference.[35]

There is a mouse model of BA where just-born mice can be inoculated with rotavirus (or reovirus or CMV) and who developed jaundice with intrahepatic histology similar to that of BA.[36,37] The nature of the cholangiodestructive pathway can be examined relatively easily, and it can be shown that there is early upregulation of interferon inducers Irf7 and Irf9 genes (proinflammatory genes), with IFN-γ having greater expression at the time of bile duct obstruction.[38–40]

If not actual virally mediated damage, then it may be that we have to postulate another way of cholangiolar damage by suggesting that the virus acts as a trigger and that in some way, there is an immune-mediated destructive process.[19] One would suspect, however, that this process would continue postportoenterostomy and that no native livers would ever drain bile in the long term. There is no real observational evidence that liver loss is inevitable though.

An interesting and novel mechanism of immune damage has been recently suggested based on the observation that

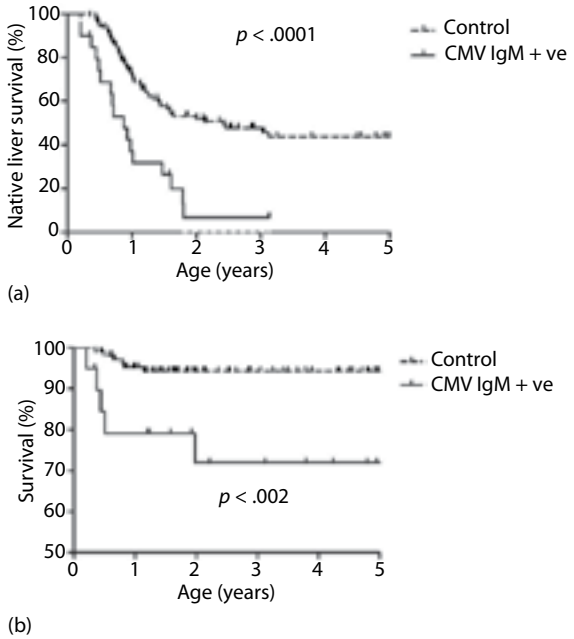

Figure 75.3 Effect of CMV IgM status on **(a)** actuarial native liver survival and **(b)** actuarial true survival. CMV IgM positive (n = 20) versus CMV IgM negative (n = 111) (dotted line). Difference between curves is significant ($p < .0001$ and $p < .002$, respectively). male BA infants have a threefold increase in maternal-origin cells in their livers.[41] These were later shown to be maternal-origin chimeric CD8+ T cells and CD45 NK cells and certainly appear capable of initiating immune cholangiolar damage.[42] This is termed *maternal microchimerism*, and it may be the reason that the destructive process is time limited.

ENVIRONMENTAL ISSUES

There have been outbreaks of BA in commercial farming. One particular famous example was reported from Burrinjuck, New South Wales, Australia, where a specific relationship with pregnant sheep grazing on land around a dam was shown. During a drought, the foreshores of the dam became exposed and colonized by a particular weed known as the red crumbweed (*Dysphania glomulifera* subsp. *glomulifera*). Almost 200 lambs subsequently born were affected by BA-like pathology.[43] In later years, whenever the exact combination of exposed foreshore, weed proliferation, and grazing pregnant livestock occurred, affected offspring were born.

This concept was further developed in the laboratory using the zebra fish model, where the genome can be manipulated and tracked as the larvae are transparent and have a fully developed biliary system by 5 days postfertilization. Potential hepatotoxic compounds derived from the various isoflavonoids found in the red crumbweed identified one, now known as *biliatresone,* which caused biliary maldevelopment[44] (Figure 75.4).

It is possible therefore that BA could arise as a result of maternal exposure to this particular toxin although not likely to be the weed itself there may be similar compounds or metabolism of non-toxic precursors such as betavulgarin which are found in more common plant foods such as sugar beet, beetroot, and chard.[45]

EPIDEMIOLOGY

Given that BA appears to be a diverse disease, it is not surprising that its epidemiology also varies. Infants with *developmental BA* have a marked female predominance not seen in the *isolated BA* group.[8,9,13] Historically, there has been a suggestion of a seasonal variation in incidence,[46,47] though when examined in large national studies, this has never been confirmed.[13,48] The implication if there were more infants with BA born during the winter months is that this might be related to the usual prevalence of viruses during this season.

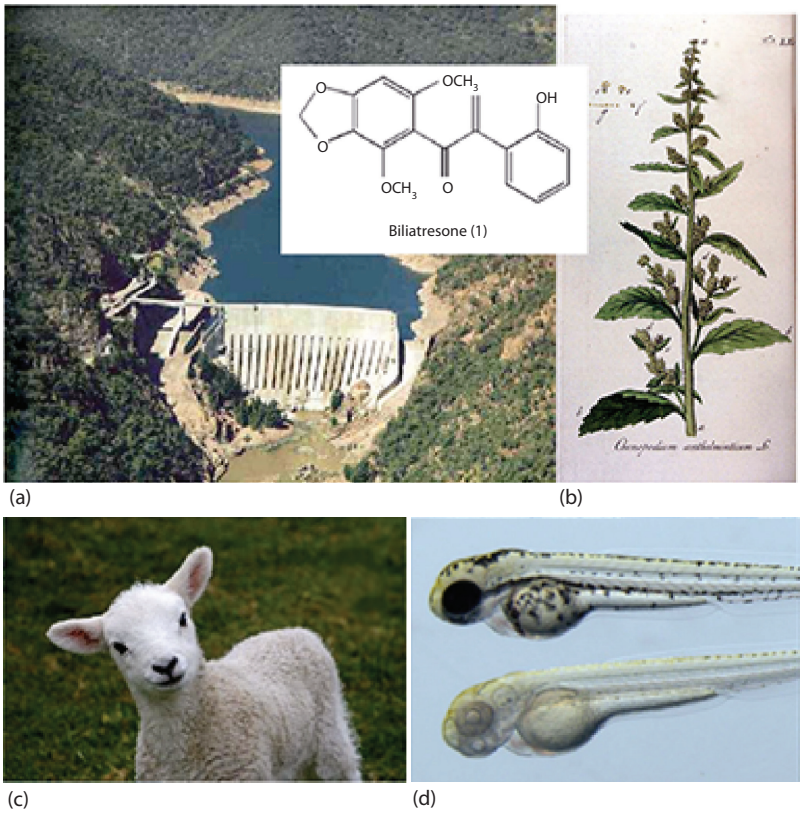

Figure 75.4 The biliatresone story: **(a)** Burunjuk Dam in Australia; **(b)** periods of drought and falling water levels allowed proliferation of the red crumbweed around the foreshore. **(c)** Pregnant ewes were allowed to graze with the following year's lambs developing biliary atresia–like pathology. **(d)** The isolated compound biliatresone was tested for its effects on developing bile ducts in zebra fish larvae. (Reproduced with permission from Davenport M, Biliary atresia: From Australia to the zebrafish, *J Pediatr Surg* 2016; 51:200–5.)

The incidence of BA varies dramatically according to geography. The highest incidences are reported from Asia, with the highest from Taiwan (1 in 5000 live births).[49] In the United Kingdom and Ireland (and much of Europe), there is an incidence of about 1 in 17,000–18,000.[13,48,50] We have reported significant regional differences within the United Kingdom, with some areas having incidences usually seen only in Asia, for instance.[13] We speculate that this may be a reflection of the current multiracial nature of the United Kingdom and, indeed, variation within the different strands of BA (e.g., developmental BA was found to be commoner in infants of Caucasian origin).

CLINICAL FEATURES

In general, infants with BA are born smaller at birth (both developmental and isolated) and fail to thrive thereafter due to fat malabsorption.[13] Antenatal detection is possible in cystic BA, and some syndromic cases may present very early because of their other malformations (e.g., malrotation, cardiac abnormities).[51]

Otherwise, the key features are conjugated jaundice together with pale, unpigmented stools and dark urine (bilirubinuria) in an otherwise healthy neonate. Liver fibrosis and cirrhosis are later developments (even in infants with intrauterine BA evident at birth),[51] and ascites and marked hepatosplenomegaly are rare features not usually seen until about 3 months.

Some infants will present with a bleeding tendency that may be catastrophic, detectable with an elevated INR or prothrombin time, and caused by fat-soluble vitamin K deficiency. This feature was particularly obvious in a recently published study in Asian-origin infants born in the United Kingdom.[52] It also tends to persist post-Kasai even if appropriately supplemented.

LABORATORY FINDINGS

Liver biochemistry will show a conjugated jaundice (variable, but rarely >250 μmol/L), modestly raised transaminases (AST > 100 IU/L), and significantly raised γ-glutamyl transpeptidase (GGT, >200 IU/L). None of this is specific.

The usual differential of a conjugated jaundice is medical and includes TORCH infections (e.g., toxoplasma, rubella, CMV, hepatitis, etc.), genetic conditions (e.g., α-1-antitrypsin deficiency, Alagille's syndrome, progressive familial intrahepatic cholestasis (PFIC) disorders, metabolic conditions (e.g., cystic fibrosis, galactosemia), and parenteral nutrition, together with something termed *neonatal hepatitis*, which is fairly nonspecific but none of the above.

The surgical differential diagnosis is less common and includes obstructed choledochal malformation, inspissated bile syndrome (usually involving the preterm), and spontaneous perforation of the bile duct.[53] The key feature in all these is that they all are able to dilate their intrahepatic bile ducts when obstructed and therefore should be distinguishable simply on ultrasound (US).

ULTRASONOGRAPHY

Ultrasound typically shows a shrunken, atrophic gallbladder with no evidence of filling between feeds. About 20% will show a "normal" gallbladder—which turns out to be a mucocele of the gallbladder in continuity with a relatively preserved CBD and, often, absence of the CHD.

Some centers appear able to actually diagnose BA, simply on US findings.[54,55] However, this is not the experience of other large institutions.[56] A specific finding is said to be the "triangular cord sign" described initially in Korean centers[54] and representing the proximal solid biliary remnant lying in front of the bifurcation of the portal vein. Accuracy rates of >80% have been reported.[55]

MISCELLANEOUS DIAGNOSTIC TECHNIQUES

In King's College Hospital, the prelaparotomy diagnosis of BA is usually made by percutaneous liver biopsy showing histological features characteristic of large duct obstruction, and this is perhaps all that is needed in >80% of cases. It is less accurate the younger the liver, though, and does require an experienced and confident liver pathologist to distinguish these very subtle features.

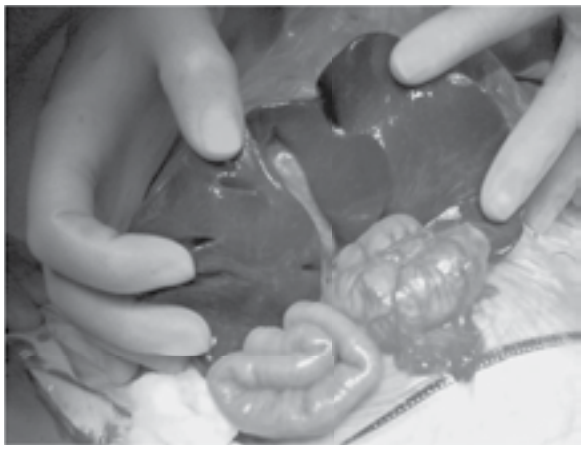
Other investigations have been reported but are not necessarily essential in every case. Radioisotope (technitium [Tc]-labeled iminodiacetic acid derivatives) hepatobiliary imaging has a role in some centers in showing the need for laparotomy by demonstrating absence of excretion, recognizing that severe forms of medical cholestasis also show this appearance.[57] A far simpler test is placement of a nasoduodenal tube and aspiration over 24 hours, and it is used in many Asian centers with undeniable accuracy but has never really been used in UK or North American centers.

Direct cholangiography is possible and is becoming more popular in those larger centers able to justify the small side-viewing endoscope necessary for infantile ERCPs.[58,59] Failure to cannulate the bile duct is a feature of BA but also may be the result of an inexperienced operator.[50] The current problem with this approach is that such scopes are no longer supported by their usual manufacturer, making repair and replacement difficult.

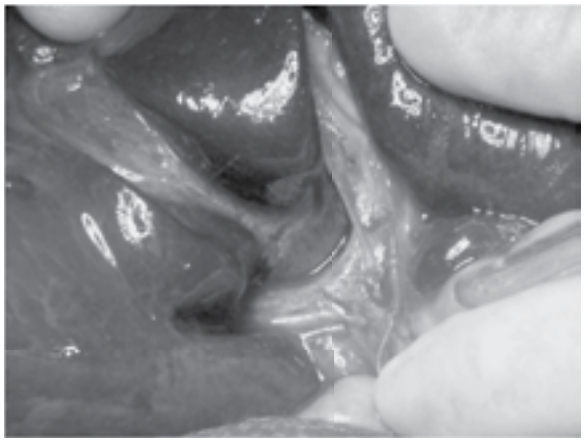
Diagnostic laparoscopy and cholangiography (± liver biopsy) is a more widely available alternative to ERCP. Direct puncture of the gallbladder is straightforward to show presence or absence of bile, and a catheter or needle can then be used to outline the biliary tree. If an atrophic gallbladder is present without a lumen, this in itself is evidence of BA and warrants further open exploration.

SURGERY—KASAI PORTOENTEROSTOMY

The preoperative management includes correcting the coagulopathy and maybe an antibacterial bowel preparation. Perioperative antibiotics should be effective against aerobic



(a)



(b)

Figure 75.5 Operative appearance of liver in biliary atresia. **(a)** The liver has been mobilized and is laid out on the anterior abdominal wall. The gallbladder is collapsed and contains no bile, consistent with a type 3 BA. **(b)** The biliary remnants and gallbladder have been removed, leaving a proximal transection of the portal plate flush with liver capsule.

and anaerobic bowel flora. The various stages in this operation can be broken down into the following (Figures 75.5 and 75.6).

Cholangiogram

The diagnosis is always confirmed initially through a limited right-upper-quadrant muscle-cutting incision, allowing access to the gallbladder. To reiterate, the key observation, confirmed by needle aspiration, is presence or absence of bile. Practically, the former can only be caused by a type 1 BA, but more likely, it indicates one of the *medical* causes of a conjugated jaundice listed previously. A cholangiogram should be done to confirm. This may not be possible in some simply because the gallbladder has no lumen—but this in itself is indicative of BA. A "normal" cholangiogram for completeness should show proximal intrahepatic ducts, and sometimes, this can be difficult, so a small vascular or bulldog clamp on the CBD should aid reflux into the more proximal ducts. Neonatal sclerosing cholangitis (a fairly controversial diagnosis) and various hypoplastic biliary syndromes (e.g., Alagille's syndrome) can then be detected.

Mobilization and eversion of liver

I believe that the most consistent and efficient dissection of the porta hepatis is facilitated by mobilization of the liver. This need not involve division of all the suspensory ligaments and can be limited to just the falciform and the left triangular and still allow the entire organ to be everted onto the anterior abdominal cavity. Care should be taken to warn the anesthetist as this maneuver kinks the cava and reduces venous return.

Portal dissection

Mobilize the gallbladder off its bed and divide the distal CBD. This allows the more proximal biliary remnant to be dissected free from the vascular elements of the porta (right hepatic artery and bifurcating portal vein). Ligate or coagulate portal lymphatics to facilitate exposure. There are always small veins passing from the superior part of the U-shaped portal vein to the portal plate—these also need careful ligation—and then the liver tissue of the caudate lobe should be seen, opposite the undersurface of segment IV. The limit of the left-sided dissection is within the recessus of Rex where the umbilical vein is in continuity with the left portal vein. If this fossa is not open, then the isthmus can be coagulated and divided. The right vascular pedicle divides into right anterior (at the base of the gallbladder bed) and posterior (lying in a small transverse depression, known as Rouviere's fossa) branches, each with an accompanying bile duct remnant. All remnant biliary tissue needs excision, and there is a definite plane of dissection from the capsule of the liver, which can be accessed using scissor dissection. Deeper dissection actually into liver parenchyma ("coring") does not seem to achieve anything useful possibly because of subsequent scarring and occlusion. Avoid coagulation on the portal plate itself and tolerate any bleeding from the edge, which will stop once the Roux loop is sutured in place.

Roux loop and portoenterostomy

A retrocolic Roux loop is constructed measuring 40 cm with the jejunojejunostomy about 10–15 cm from the ligament of Trietz (to get mobility and reduce anastomosis tension). The portoenterostomy must incorporate all the denuded portal plate and should be quite wide (at least 2 cm). I prefer an end-to-side arrangement using fine (e.g., 6/0 PDS) sutures, although other authors argue for an end-to-end arrangement.[60] A second layer can be added at the end posteriorly using adjacent periportal tissue.

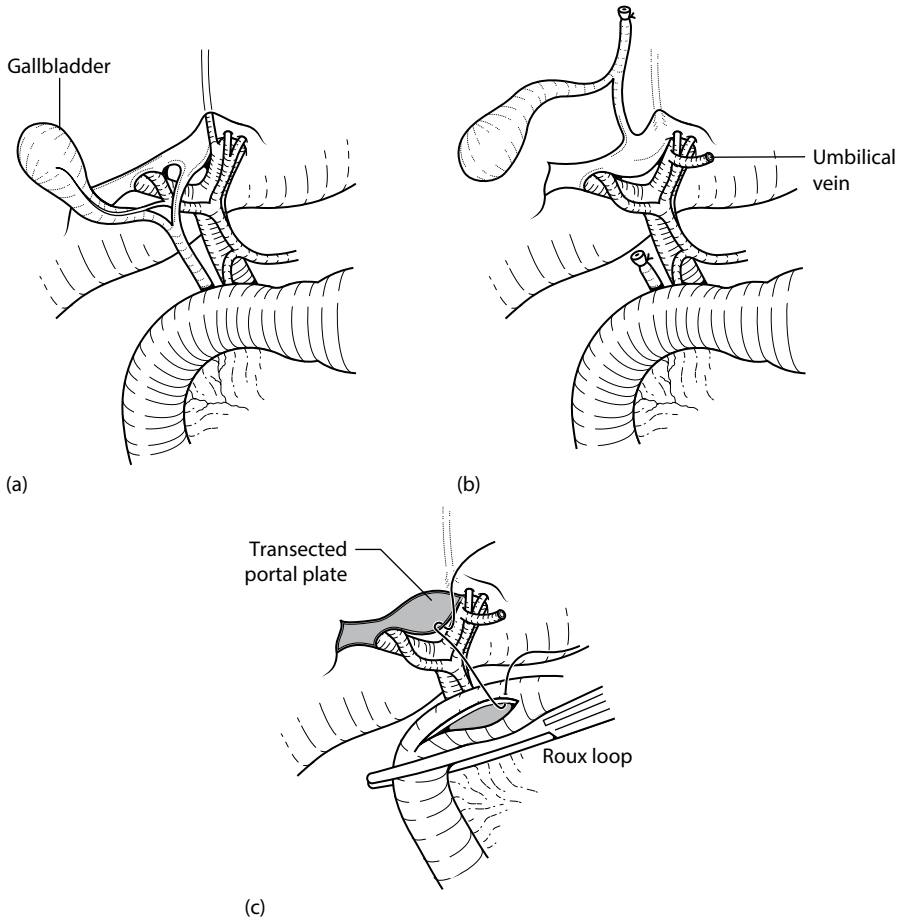


Figure 75.6 Schematic illustration of Kasai portoenterostomy. **(a)** Type 3 biliary atresia. **(b)** Mobilization of gallbladder and division of distal common bile duct. Elevation of biliary remnants and separation from vascular structures at level of porta hepatis (portal vein confluence, right and left hepatic arteries). **(c)** Transection of portal plate from "umbilical point" on left, to around right portal pedicle. Portoenterostomy with 40–45 cm retrocolic Roux loop.

Wound closure needs care as postoperative ascites can test its integrity and strength to the limit. A small drain may help to minimize ascite retention and allow the wound layers to heal. Significant bile leaks don't happen in Kasai operations—almost certainly because there's not that much bile around to leak!

CAVEATS TO SURGERY

Although visible bile-containing ducts may be evident in type 1 or 2 BA and a hepaticojejunostomy performed, it is better that further proximal tissue is resected to the level of (and therefore needing) a portoenterostomy.

Sometimes, on-table evidence of cirrhosis may seem to make a portoenterostomy futile. However, this is rarely absolutely predictable, although obviously more likely in infants of >100 days.[61] A primary transplant may be a better option, but this is arguable.

At times, it has been suggested that a frozen section of the resected portal plate is useful to determine whether ductules are large enough (Figure 75.7). In practice, the aim is to resect all visible bile duct remnants down to, but not encroaching on, parenchyma—thus, there is nothing further to resect whatever the pathologist reports.

Portoenterostomy in BASM has a worse long-term outcome, and the outcome can be related to the age at which the surgery is performed.[8,62] The extrahepatic bile ducts

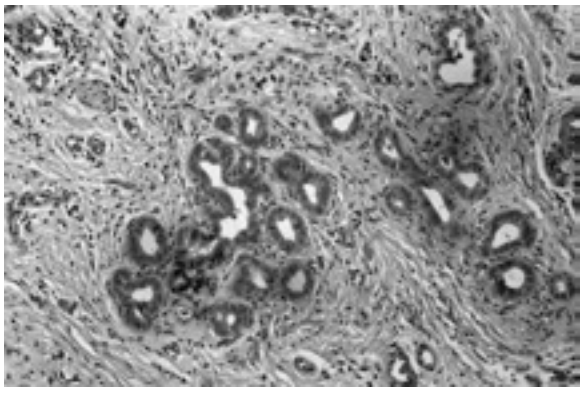

Figure 75.7 Hematoxylin and eosin microphotograph of transected biliary remnant showing multiple biliary ductules lined with relatively normal epithelium, within a fibrous stroma infiltrated by inflammatory mononuclear cells.

are rarely florid, often noninflammatory, and atrophic in appearance. Great care should be taken with the preduodenal portal vein and any aberrant arterial vessels. A malrotation may require Ladd's procedure and influence the construction of the Roux loop.

POSTOPERATIVE MANAGEMENT

Nasogastric drainage and intravenous fluids are required for 2–4 days before starting feeds. There is no clear advantage from continuing prophylactic antibiotics beyond 1 month, though it is the practice of many centers.

All infants, even those rendered anicteric, require fat-soluble vitamin supplementation (both enteral and parenteral), and levels should be monitored assiduously.[52] They should also have access to an appropriate formula milk (e.g., containing medium-chain rather than long-chain triglycerides). Failure to thrive should be aggressively attended to, with nasogastric overnight feeds if necessary. The medical management of the infant or child with serious underlying liver disease is complex, demanding, and absolutely crucial. Most centers achieve this successfully using a multidisciplinary team approach.[63]

Pharmacological improvement in bile flow is possible, by ursodeoxycholic acid, for instance, but only when a degree of flow has been established by surgery and is one of the postulated mechanisms for steroids.[63,64] There is not much evidence for other medications, although a number of Japanese and Chinese centers use the Chinese herb Inchinko-to.[65]

The use of steroids is controversial but appealing, given the possible role of inflammation in the etiology of BA. Actual evidence is somewhat contradictory. Our randomized placebo-controlled trial of oral prednisolone (2 and then 1 mg kg^{-1} day^{-1} in the first month) showed definite improvements in early clearance of jaundice but a lack of a real effect on final results and a need for transplant.[64] We then followed this using an open-label trial and a higher dose (starting at 5 mg kg^{-1} day^{-1}), which showed a statistically significant 15% increase in clearance of jaundice compared to control and placebo in those <70 days at Kasai portoenterostomy.[66] By contrast, a North American placebo-controlled trial came to a different conclusion of "no effect" despite showing the same degree of difference but with smaller numbers in the groups to be compared—hence not reaching statistical significance.[67] There is also evidence emerging to suggest that this early effect may translate to an improved native liver survival rate.[68]

OUTCOME FOLLOWING PORTOENTEROSTOMY

The actuarial 5- and 10-year survival in England and Wales for infants born this century is about 90%[7,69] (Figure 75.8). There will still be deaths: most awaiting transplantation, some as postoperative complications due to transplant, and some due to the lethal effects of other anomalies (e.g., cardiac).

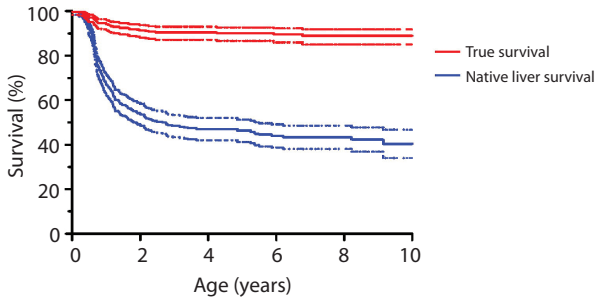

Figure 75.8 Actuarial true and native liver survival curves (median [±95% CI]) for BA (n = 443) in England and Wales (1999–2009). (Reproduced with permission from Davenport M et al., Biliary atresia in England and Wales: Results of centralisation and a new benchmark. *J Pediatr Surg* 2011; 46:1689–94.)

We would expect to restore enough bile flow to clear jaundice and achieve normal values for bilirubin in about 50%–60% of infants with isolated BA.[7,69] Most (>90%) of these infants can expect to survive long term with a relatively normal childhood but regular outpatient attendance to monitor progress. Their livers will however seldom be normal, however; in fact, if ever biopsied, they will be highly likely to show histological cirrhosis.[70] The 5- and 10-year native liver survival will be about 45%–50%, therefore.[7,69,70] Care should be taken in the interpretation of such figures if they are from countries with no transplant option, as their native liver survival equates to true survival.[71]

Effect of age at surgery

Cirrhosis and fibrosis are time-dependent phenomena, and it is very reasonable to surmise that the earlier in the disease the cirrhotic process is abbreviated by restoration of bile flow, the better the outcome. However, as stated earlier, BA is a heterogenous disease; especially in isolated BA, the time of onset is not known, and trying to identify a real effect of age on a large series can be difficult (Figure 75.9).[7,71–74] This hypothesis is supported by the observation that in those where there is definite evidence of intrauterine pathology (i.e., developmental BA), there is a marked relationship, while in those described as isolated (presumably much more chronologically heterogenous), this relationship is not seen (within 100 days at least).[55]

Figure 75.10 illustrates this problem. The group is as homogenous as possible, being only infants with isolated BA, and is derived from a single center with two surgeons using the same technique and outcome measured with defined end points (clearance of jaundice). Statistically, as the compendium solid black line is *virtually* flat, this implies no "cutoff" and no effect of age within pragmatic limits. There is actually a *gradual* decline, implying the truth of the original postulate (age worsens outcome) but statistically will require many more numbers to prove it.

Is there any benefit of surgery to those infants who come to surgery at >100 days? Though this is now relatively

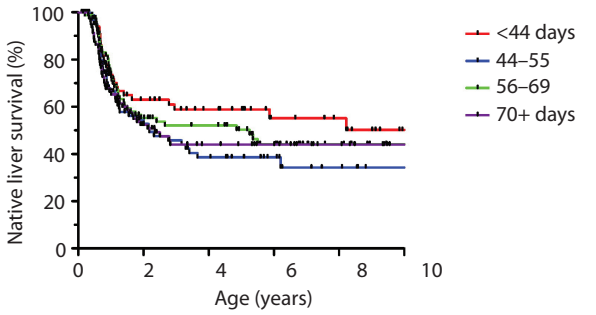

Figure 75.9 Effect of age at Kasai portoenterostomy. Infants with isolated BA (n = 318) were divided by age at surgery. No difference overall (χ = 3.3; p = .34) or for trend (χ^2 = 0.87; p = .35). Specifically, no difference between two outermost curves (χ^2 = 2.1; p = .15). (Reproduced with permission from Davenport M et al., Biliary atresia in England and Wales: Results of centralisation and a new benchmark. *J Pediatr Surg* 2011; 46:1689–94.)

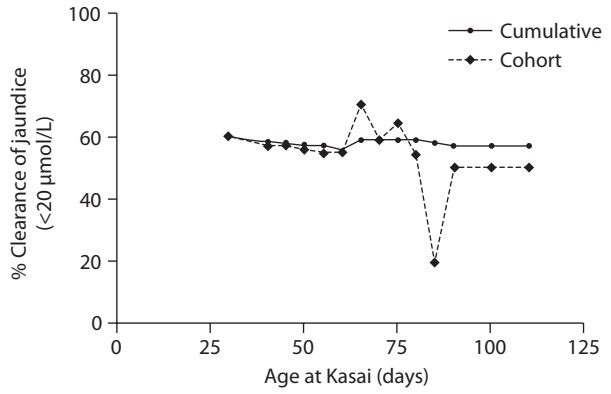

Figure 75.10 Relationship of age at surgery to clearance of jaundice in infants with isolated biliary atresia (n = 177). (Reprinted with permission from Davenport M et al., Surgical outcome in biliary atresia: Etiology affects the influence of age at surgery, *Ann Surg* 2008; 247:694–8.)

infrequent in developed countries, it still occurs. That they are much more likely to have established cirrhosis is true, and their prognosis is certainly less good. Nevertheless, a Kasai as the first step seems reasonable and has been associated with long-term jaundice-free survival in our series.[61] The alternative, of course, is a primary liver transplant.

COMPLICATIONS

Apart from end-stage liver disease in those where there is failure to restore bile flow with development of ascites, malnutrition, and deepening jaundice and that clearly can only be treated by transplantation, there are two major areas of complication.

Cholangitis

This probably occurs in relation to ascending organisms from within the Roux loop, as cholangitis is rare in those who never show any degree of bile flow post-Kasai. It is reported in up to 50% of large series but seems only to be problematic in the first year postsurgery. It may be characterized by pyrexia, pale stools, increasing jaundice, and other signs of sepsis. Culture of organisms from blood or from liver biopsy is uncommon, and judicious use of early, broad-spectrum antibiotics is advised (e.g., ceftazidime, gentamicin etc.).

Recurrent cholangitis may occur possibly due to the formation of dilated biliary channels or cystic change within the liver acting as a nidus for infection. This should be obvious on US. Unless the cystic change is gross and the underlying liver function good, then this should probably be managed conservatively with prolonged antibiotics, often via a Hickman line. In those who do meet these criteria, it is usually possible to access the cystic change surgically and incorporate it into the preexisting Roux loop. In some cases, there is mechanical obstruction to bile drainage within the Roux loop, and this may be detectable using a radioisotope scan.[75] In older children, newer enteroscopes are now able to visualize the Roux loop directly, and this may be an alternate mode of diagnosis. Laparotomy and Roux loop exploration and revision may be indicated.

Portal hypertension

It is possible to measure portal venous pressure via the obliterated umbilical vein at the time of Kasai portoenterostomy.[76,77] This will show that most infants will have portal hypertension (PHT), but whether this persists will more likely depend upon degree of restoration of bile flow and other dynamic factors.[77] Esophagogastric varices take time to develop but will do so given sustained periods of PHT. The majority of long-term survivors will have endoscopic evidence of varices, although only a proportion will ever bleed. Our recent series review suggested that 22% will have significant varices (having bled or ≥Grade 2).[78] Surveillance endoscopy is recommended in these, although evidence is lacking for the role of prophylactic treatment (e.g., banding). Nonetheless, this is a possible option. We have also looked at a variety of scoring formulas to predict the presence of varices in this group, with the best, the varices prediction rule, to be one involving the serum albumin level and platelet count (Figure 75.11).

Varices prediction rule (VPR):

$$VPR = \frac{Albumin \times Platelet\ count}{1000}$$

Using cutoff of ≤7.2, the sensitivity and specificity for prediction of significant varices in infants at 6 months were 86% and 71% respectively.

Figure 75.11 Varices prediction rule.

Those who have bled will require some form of endoscopic intervention initially, either sclerotherapy or banding. The former technique is well established but not without complications such as ulceration, stenosis, and stricture formation, and currently should probably be reserved for infants and smaller children where it is not possible to actually pass the banding attachment. There will be a small proportion that have variceal bleeding of such magnitude to require immediate placement of a Sengstaken tube—this is fortunately unusual and can be lifesaving.[79] Following endoscopic control of the varices, an assessment needs to be made about the overall liver reserve. There will be some with excellent restoration of liver function and clearance of jaundice where obliteration of varices is all that is needed; there will be others (typically infants and young children <2 years) where this is simply one part of a failing system, and these need to have an expedited transplant.

ROLE OF LAPAROSCOPIC KASAI PORTOENTEROSTOMY

The tsunami of minimally invasive surgery in the 1990s swept along pediatric as well as general surgeons, and soon, more and more adventurous operations were being described through smaller multiple-port incisions—including the Kasai operation. Small series have been reported but none with good results and most with only limited outcomes.[80,81] At this present time, this operation may be the limit, and a number of enthusiasts are returning to the conventional open approach,[82] though there are still exceptions. The Japanese group led by Yamataka consciously limits the resection level at the porta hepatis, suggesting that it more closely mimics Kasai's original surgery and is certainly more easily achieved laparoscopically.[83]

The reasons for failure in other peoples' hands may be self-evident though—the dissection is unforgiving, meticulous precision is required, and therefore, even with a robot, the operations are simply not comparable. Others have suggested that it may be the effect of the paraphernalia of minimally invasive surgery. For example, Mogilner et al.[84] in an experimental model showed that the higher intra-abdominal pressures of the pneumoperitoneum may increase damage through effects on liver blood flow. A definitive answer has yet to be delivered, but in its absence, practitioners should be cautious—this surgery has a high enough "failure" rate without making it more difficult, and promises of a better cosmetic result and short hospital stays are fatuous in the context of BA. The only person benefiting is the transplant surgeon, who has a reduced amount of adhesions to deal with, and they tend to leave the biggest scars of all!

LIVER TRANSPLANTATION IN BA

This has been available in North America and Western Europe for "failed" Kasai children since the 1980s. It is still a major undertaking, with a consistent risk of postoperative mortality of 6%–15%.[85–87] The risk diminishes beyond the first year, and an actuarial plateau is then reached, although the vast majority still require oral immunosuppression. A few do develop tolerance (perhaps up to 20%) with the possibility to withdraw medication.[88] Longer-term issues such as Epstein–Barr-related posttransplant lymphoproliferative disease (PTLD) (up to 10% of some series) and chronic rejection are still a cause of morbidity and potential mortality.[89]

There are, within all countries and societies, problems coming to terms with ethical attitudes to both cadaveric and living-donor transplantation. Effective use of donor organs and, as a consequence, waiting-list death is still a major issue. There are also lingering technical issues related to size discrepancy, although organ reduction and split-liver transplants ameliorate this in the larger centers.

In conclusion, BA in many respects remains a mysterious disease with its origins cloaked and obscure; in others, though, the need for surgical intervention is straightforward, and the outcome may be somewhat capricious and unpredictable.[79] We believe that centralization of resources is one way to maximize outcome, and this appears to be the pattern now followed in the Netherlands, Denmark, Israel, and Finland. Geographic considerations clearly must play a large role in this, but surely, the time for your Kasai surgeon to be doing one or two a year should be over. Future needs will include better pharmacological options to improve bile flow post-Kasai and modify or at least abbreviate the invariable tendency to liver fibrosis (and hence PHT). This particular characteristic is a real risk to the life of a small infant on a transplant waiting list.

Congenital biliary dilatation

HIROYUKI KOGA AND ATSUYUKI YAMATAKA

INTRODUCTION

Congenital biliary dilatation (CBD), or choledochal cyst, is a cystic or fusiform dilatation of the common bile duct that is uncommon in Caucasians. There is little doubt that CBD is a congenital lesion with a strong hereditary component, which may explain the higher incidence seen in Asia, and its familial occurrence in siblings and twins.[1–3] Traditionally, approximately half become symptomatic in infancy, and neonatal cases have been uncommon. However, with advances in diagnostic imaging techniques, its incidence is increasing, particularly in neonates because of an increase in prenatally diagnosed CBD.[4–12] In our series, about 20% of patients were detected either neonatally or antenatally, and interestingly, the ratio of cystic to fusiform-type CBD neonatally or antenatally is 20:1, in contrast to an overall ratio of 5:3.[13]

The treatment of CBD in early infancy has unique aspects that must be considered in relation to the risks of surgery itself and the size and physiological/immunological immaturity of the patient. Because CBD is commonly associated with pancreaticobiliary malunion (PBMU) involving concurrent anomalies of the common channel, pancreatic duct, and intrahepatic bile duct (IHBD), the importance of cholangiography both preoperatively and intraoperatively cannot be overemphasized. If these anomalies go unnoticed by surgeons, they may lead to injury during surgery and cause serious postoperative morbidity. Primary cyst excision (CE) with biliary reconstruction to avoid two-way reflux of bile and pancreatic secretions is now the standard procedure of choice.

ETIOLOGY

Various theories have been proposed for the etiology of CBD, but two factors are known to be causal—weakness of the wall of the common bile duct and obstruction distal to it. Spitz[14] stressed an obstructive factor that appears early in development based on his experimental study in sheep, in which cystic dilatation of the common bile duct could be induced by ligation of the distal end of the choledochus only in neonatal lambs and at no other stages of development. The author's animal research has confirmed this hypothesis,[15–19] and our radiologic and histologic studies on patients with CBD clearly demonstrate that distal stenosis is closely associated with cystic dilatation of the common bile duct, and that the site of stenosis is related to an abnormal choledochopancreatic ductal junction.[16,19,20] Jona et al.[21] purported that the pathogenesis of CBD-associated PBMU may be related to faulty budding of the primitive ventral pancreas. Wong and Lister[22] conducted research on human fetuses and demonstrated that the choledochopancreatic junction lies outside the duodenal wall before the eighth week of gestation, whereupon it moves inward toward the duodenal lumen, suggesting that an anomalous junction may be caused by arrest of this migration, while Tanaka[23,24] proposed that regression of the terminal choledochus and canalization of the ventral pancreatic duct (W1) caused by sinistral dislocation of the ventral pancreas are responsible for PBMU.

In recent years, cholangiography has identified anomalies of the pancreaticobiliary ductal system in association with CBD, which may allow reflux of pancreatic enzymes and subsequent dissolution of duct walls. This is known as the long common channel theory and was first proposed by Babbit in 1969.[25] Since then, numerous abnormal arrangements of the pancreaticobiliary junction associated with CBD have been reported by others based on the results of endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic cholangiography, and intraoperative cholangiography. This theory is further supported by the high amylase content of fluid aspirated from dilated ducts in patients with CBD. A dilated common channel and anomalous pancreatic duct are also frequently observed, which may be responsible for the formation of protein plugs or pancreatic stones, often associated with pancreatitis. It is generally recognized that a number of patients with an anomalous long common channel and high amylase level in the gallbladder show no dilatation of the choledochus, although some had gallbladder carcinoma.[26] But, the

authors' research in which choledochopancreatostomy was performed in puppies to allow regurgitation of pancreatic fluid into the common bile duct found that the chemical reaction of refluxed pancreatic fluid in the bile duct was extremely mild.[27] Interestingly, in this animal model, fusiform rather than cystic dilatation of the common bile duct was induced.

Although Babbit[25] stressed that pancreatic fluid is the most likely factor causing edema and eventual fibrosis of the distal common bile duct as well as weakness of the choledochal wall, a diagnosis of CBD can be made antenatally as early as 15–20 weeks' gestation,[9–11,28] at which time pancreatic acini are only just beginning to appear, zymogen granules are immature, and there is no evidence of secretion seen on electron microscopy.[29] Thus, the chemical reaction of pancreatic fluid on the bile duct has not been clarified in the antenatal period, and even in the neonate, the pancreas has not matured enough to produce functional enzymes,[30] so the role of pancreatic fluid in CBD formation may be overrated.

In spite of these findings, controversy surrounds the cause of the stenosis distal to the dilated common bile duct. The authors believe that an anomalous choledochopancreatic duct junction and congenital stenosis are the basic causative factors of CBD, at least in perinatal and young infants, rather than weakness of the duct wall caused by reflux of pancreatic fluid. Both PBMU and stenosis are associated with abnormal development of the ventral pancreatic duct and biliary duct system.

CLASSIFICATION

Alonso-Lej et al.,[31] Todani et al.,[32] and Komi et al.[33] have described classifications for CBD based on anatomy and cholangiography of the hepatobiliary duct system or PBMU. Classification based on the association with PBMU is presented in Figure 76.1.

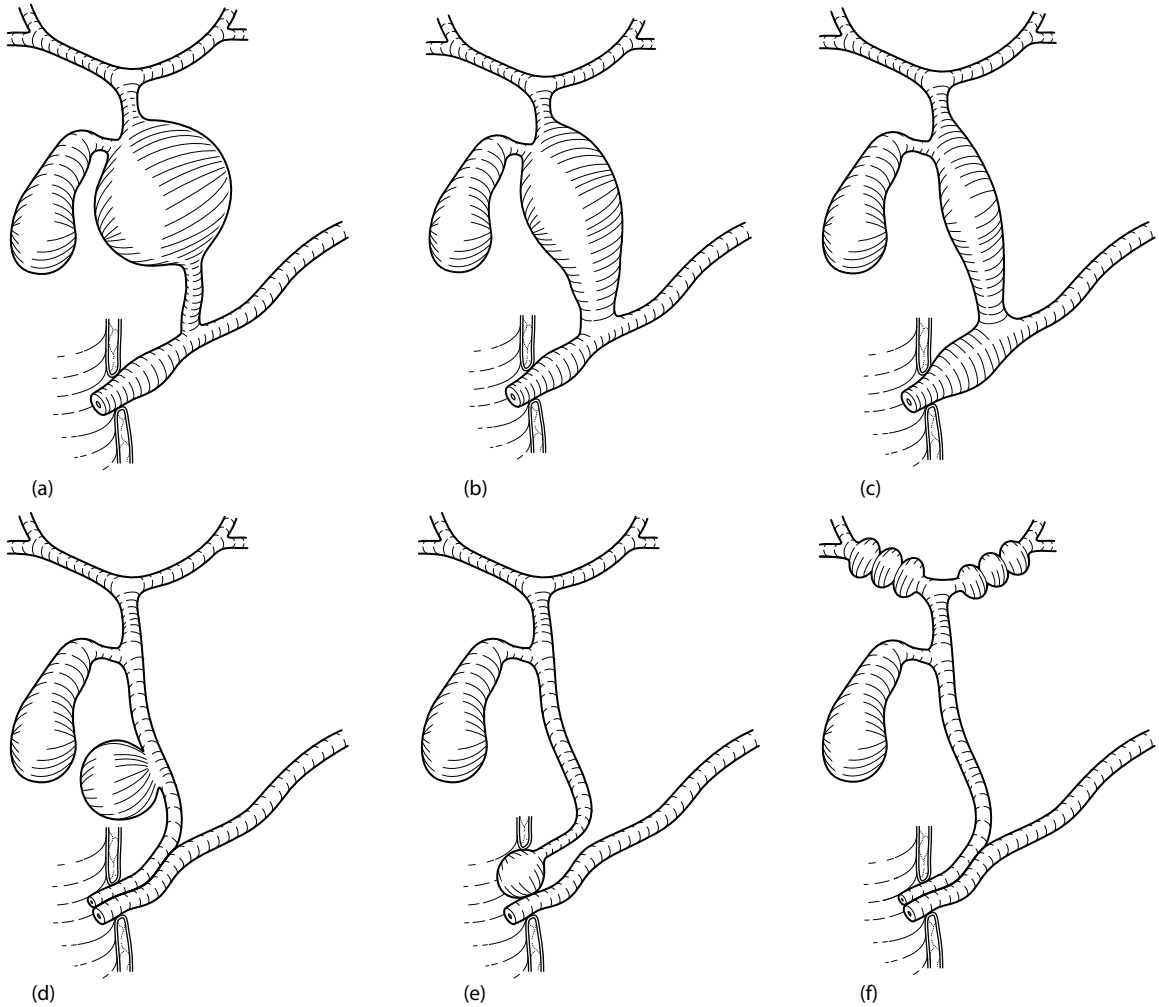

Figure 76.1 Classification of congenital biliary dilatation with PBMU. **(a)** Cystic dilatation of the extrahepatic bile duct. **(b)** Fusiform dilatation of the extrahepatic bile duct. **(c)** Forme fruste type. Without PBMU. **(d)** Cystic diverticulum of the common bile duct. **(e)** Choledochocele (diverticulum of the distal common bile duct). **(f)** Intrahepatic bile duct dilatation alone (Caroli disease). (With kind permission from Springer Science+Business Media: *Pediatric Surgery*, Puri P., Hollwarth M. (eds), Springer Surgery Atlas Series, 2006, p. 373, Miyano T., Urao M., Yamataka A., figure 34.1a–f.)

CLINICAL SIGNS AND SYMPTOMS

Clinical manifestations of CBD differ according to age. Neonates and young infants usually present with an abdominal mass, or obstructive jaundice, and acholic stools, depending on the degree of obstruction. Some present with a huge upper abdominal mass with or without jaundice. Some cases can even resemble correctable biliary atresia except that with CBD, there is a patent communication with the duodenum and a well-developed IHBD tree. In older children, the classical triad of pain, mass, and jaundice may be present. Fever and vomiting may also occur. The pattern of pain has been described as being similar to that of recurrent pancreatitis, in which a high serum amylase level is often present. However, in our series, there was no clinical evidence of pancreatitis in the neonate, and amylase levels were not found to be elevated. CBD should always be considered in the differential diagnosis of a child with abdominal signs and symptoms; the essentials of management are the same. Furthermore, we should keep in mind that there may be an association of the malignancy at the time of primary CE. The youngest case of cholangiocarcinoma associated with CBD at the time of primary CE is a 3-year-old boy.[34] Recently, we also encountered a 3 year-old boy who was found to have a carcinoma in situ in the cyst at the time of primary CE.

DIAGNOSIS

Currently, abdominal ultrasonography (US) is the best method for detecting CBD, even though it does not permit visualization of the entire duct system and is also not sensitive enough to demonstrate a non-dilated common channel and pancreatic duct. However, routine antenatal US performed mainly for dating purposes has been of increasing value for detecting fetal anomalies,[4–11,28] and the number of neonates detected as having incidental CBD has increased significantly (Figure 76.2). CBD has been detected at routine prenatal ultrasound examinations as early as 15 weeks' gestation.[9,10] Typical findings on high-resolution US are of a cyst in the porta hepatitis. These findings may be confused with duodenal atresia, biliary atresia, ovarian cysts, duplication cysts, and mesenteric cysts. Having a skilled and experienced sonologist performing the prenatal ultrasound has been critical in increasing both the sensitivity and specificity of prenatal ultrasound for CBD. Fetal magnetic resonance imaging (MRI) has additionally been performed to aid in the diagnosis. Both imaging techniques may increase the diagnostic yield in a complementary fashion.

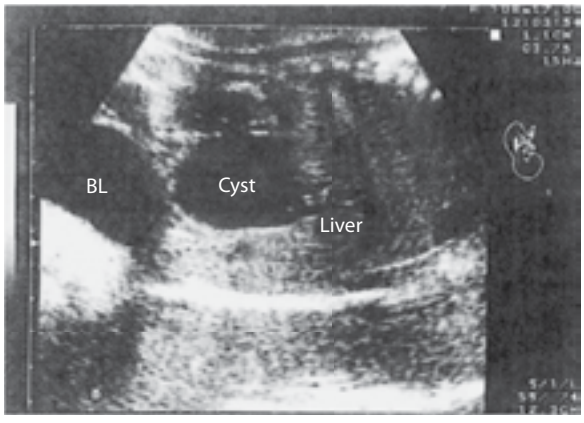

Figure 76.2 Antenatal ultrasound at 32 weeks' gestation. Sagittal view. A cystic structure is seen to be connected to the liver via a short duct (arrow). BI: bladder. (From Miyano T., Yamataka A., in Puri P. (ed), *Newborn Surgery* (2nd ed), Edward Arnold, p. 591, figure 62.2, 2003; same figure.)

For thorough assessment of CBD, it is important to investigate for coexisting PBMU, and anomalies of the pancreatic duct, intrahepatic ducts, and extrahepatic duct. ERCP can accurately delineate the configuration of the pancreaticobiliary duct system in detail and is unlikely to be replaced by other investigations, especially in cases where fine detail is required preoperatively. In the past, ERCP was routinely performed for the diagnosis of biliary malformations in infants and neonates in many centers in Japan, with a reasonable success rate.[35] However, it is an invasive procedure, especially in children, and therefore is unsuitable for repeated use and is contraindicated during acute pancreatitis.

The authors and others[36,37] have shown that magnetic resonance cholangiopancreatography (MRCP) can provide excellent visualization of the pancreaticobiliary ducts in patients with CBD, allowing narrowing, dilatation, and filling defects of the ducts to be detected with medium to high degrees of accuracy (Figure 76.3). Because MRCP is noninvasive, it can partially replace ERCP as a diagnostic tool for the evaluation of anatomic anomalies of the pancreaticobiliary tract, where it is available, but there are limitations of patient size, weight, and age for the use of MRCP. Another advantage of MRCP over ERCP is that the pancreatic duct can be visualized upstream to an obstruction or area of stenosis. Due to the improved quality of MRCP, ERCP, nowadays, is rarely indicated.

If preoperative imaging can allow clear visualization of the entire biliopancreatic ductal system, including the intrahepatic and extrahepatic bile ducts, and pancreatic duct in detail, intraoperative cholangiography is unnecessary; however, if sufficient information is not obtained, it must be performed. Furthermore, if the cyst is too large, intraoperative cholangiography via the gallbladder or directly via the common bile duct is useless. In such cases, intraoperative cholangiography should be performed separately for the IHBD and distal common bile duct by a selective technique during CE.

SURGERY

Choice of operative procedures

CE is currently the definitive treatment for CBD regardless of age or symptomatology because internal drainage, a commonly used treatment in the past, is associated with high morbidity and high risk for carcinoma. Basically, the only

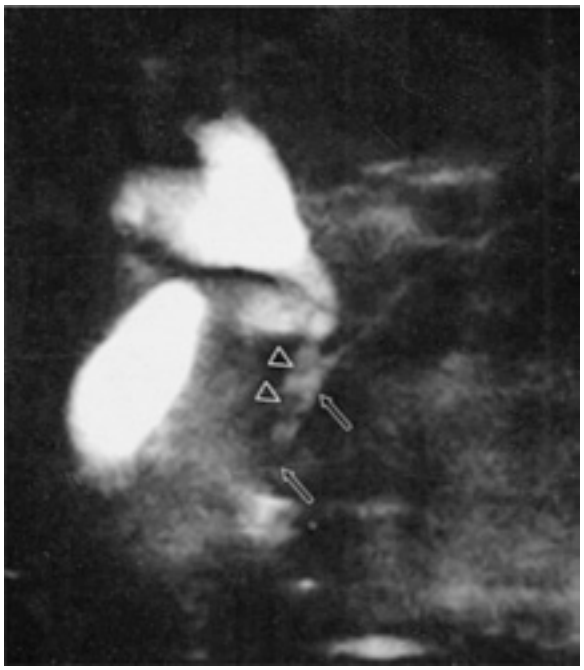

Figure 76.3 Magnetic resonance cholangiopancreatography (MRCP) in a patient with congenital biliary dilatation showing fusiform dilatation of the extrahepatic bile duct, long common channel (between arrows), protein plugs (arrowheads), and pancreatic duct. (With kind permission from Springer Science+Business Media: *Pediatric Surgery*, Puri P., Hollwarth M. (eds), 2009, p. 548, Yamataka A., Kato Y., figure 56.2.)

difference between operative procedures available is the type of biliary reconstruction performed, although the level of transection of the common hepatic duct and the level of excision of the intrapancreatic bile duct are controversial. Although most surgeons use a Roux-en-Y hepaticojejunostomy, some[38,39] recommend a wide anastomosis at the level of the hepatic hilum to allow free drainage of bile in order to prevent postoperative anastomotic stricture and stone formation. The authors[40] recommend conventional hepaticojejunostomy, while others prefer hepaticoduodenostomy. Whatever type of biliary reconstruction is used, satisfactory surgical outcome with low early morbidity is to be expected, but postoperative complications after CE, especially in the long term, generally occur more often if dilated IHBD is present. In our experience, hepaticoduodenostomy is not ideal for biliary reconstruction because of a high incidence of complications due to duodenogastric bile reflux.[40] Todani et al.[41] encountered a case of hilar bile duct carcinoma that developed 19 years after primary CE and hepaticoduodenostomy. Although Todani's team preferred hepaticoduodenostomy because they believed it was more physiologic, they have since abandoned hepaticoduodenostomy after CE and now perform hepaticojejunostomy. However, in the laparoscopic era, there are increasing reports concluding that laparoscopic CE with hepaticoduodenostomy is safe and feasible and is not inferior to hepaticojejunostomy,[42] and furthermore, that laparoscopic CE with both hepaticojejunostomy and hepaticoduodenostomy reconstruction appears to be safe and has equivalent outcomes to open procedures in our series.[43] However, the follow-up length in these reports is short term in all. Hepaticoenterostomy (HE) at the hepatic hilum is indicated in specific cases only, such as in patients with dilated IHBD with stenosis in the common hepatic duct, or adolescent patients with severe inflammation of the common hepatic duct.

Timing of surgery

Some pediatric surgeons recommend primary CE soon after diagnosis, including prenatally diagnosed cases;[6,8,10,44–46] however, in the authors' experience,[14,47] CE need not be performed hastily if jaundice is not present. Rather, patients should be thoroughly assessed and surgery planned and performed by experienced, well-trained pediatric surgeons. In cases of bile peritonitis following perforation, severe cholangitis, poor general condition, or huge dilated CBD in neonates, external biliary drainage is recommended by either percutaneous transhepatic cholangiodrainage or direct percutaneous cyst drainage. Subsequently, delayed CE may be carried out 1–3 months later.

Neonates with CBD should receive standard medical management and nutritional support preoperatively and postoperatively; the importance of thorough preoperative assessment cannot be overemphasized. However, the timing of surgery for neonates is highly controversial despite increasing reports about the management of asymptomatic CBD detected in the antenatal or neonatal period. Diao et al.[46] mentioned that prenatally diagnosed CBD is a distinct group with a tendency of developing liver fibrosis immediately after birth and thus, early surgical intervention is warranted in the neonatal period. However, according to the authors' experience, developing liver fibrosis in CBD is extremely rare, although there have been a few cases of neonates already having liver fibrosis at the time of diagnosis; thus, the authors believe that if the neonates are asymptomatic, they, including prenatally diagnosed cases, should not be treated in the neonatal period but instead be treated around the age of 3 months, since there is an unacceptably high incidence of anastomotic leakage if treated in the neonatal period.[48] On the other hand, neonates should be treated by early surgery if they are jaundiced or have hepatic fibrosis; for example, Dewbury et al.[4] reported that a laparotomy at 10 days of age confirmed a prenatally diagnosed CBD associated with severe hepatic fibrosis, Early surgery provides the opportunity to exclude biliary atresia; prevent biliary and hepatic complications such as liver fibrosis, which can progress rapidly in cases with biliary obstruction;[4,10,45] reverse fibrosis; reduce the risk for cholangitis; prevent accumulation of biliary sludge; relieve obstructive jaundice; as well as prevent cyst perforation.[6]

Complete excision

Complete (full-thickness) excision of the cyst is much easier in neonates and young infants, because the wall of the

dilated common bile duct is generally thin and there are few adhesions to surrounding structures, such as the portal vein.[49,50] Aspiration of the cyst prior to dissection makes surgery easier if the cyst is large. The cyst should be incised in the middle portion close to the duodenum, because there is often an anomalous opening of the hepatic duct, i.e., a separate opening or opening into the distal part of the cyst. The cyst is then transected after careful circumferential dissection from the hepatic artery and portal vein. Subsequently, the distal portion is dissected and excised, taking care to completely remove the dilated segment at the level of the caliber change in order to prevent malignant transformation of the remaining cyst epithelium. If the cyst has no distinct caliber change (i.e., fusiform), it should be excised just above the choledochopancreatic junction, and the stump double-sutured, ligated, and transected (Figure 76.4). If protein plugs are found in the common channel, intraoperative endoscopy should be used to wash them toward the duodenum to avoid postoperative stone formation and pancreatitis. Finally, the common hepatic duct is transected at the level of distinct caliber change to leave an adequate length for HE.

Mucosectomy/biliary reconstruction

If CE of the distal portion is difficult due to inflammation or adhesions, mucosectomy[45,47] of the distal portion of the cyst is recommended, in order to avoid damage to the pancreatic duct, hepatic artery, and portal vein, and also to prevent the residual epithelium of the distal portion of the cyst from undergoing malignant transformation (Figure 76.5). However, in neonates, infants, and small children, mucosectomy is rarely indicated because there is little inflammation around the cyst wall. Biliary reconstruction in neonates and infants is technically involved because anastomoses are often small and so should only be undertaken by experienced pediatric surgeons. Some surgeons overcome this problem by partially incising the mouth of the stoma of the anastomosis to widen it. On occasion, the authors have encountered luminal stenosis of macroscopically normal common hepatic ducts at the time of CE, which was considered to be secondary to fibrosis, probably as a consequence of inflammation associated with previous perforation.

Although an end-to-side anastomosis was initially used, the authors now prefer end-to-end anastomosis during Roux-en-Y hepaticojejunostomy, because drainage is more streamlined, with less possibility of bile stasis (Figure 76.6). With end-to-side anastomosis, there was overgrowth of the blind end, causing adhesive bowel obstruction between the blind pouch and jejunum in one case and stone formation in the blind pouch in another (Figure 76.7).[47] Bile stasis in the blind pouch can also cause stone formation in the IHBD dilatation at the porta hepatis. If end-to-side anastomosis is unavoidable, the common hepatic duct should be anastomosed as close as possible to the closed end of the blind pouch so there will be no blind pouch at the anastomosis

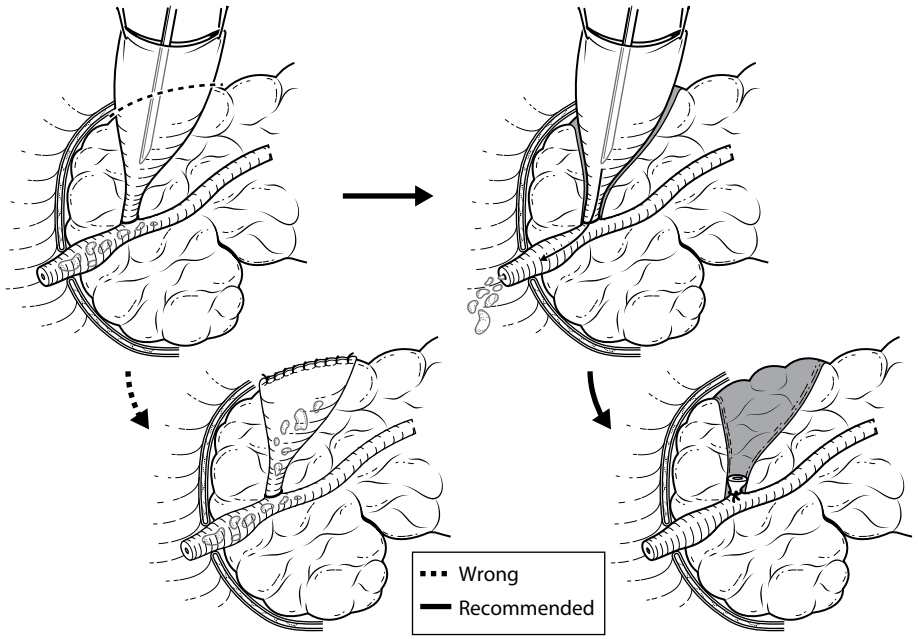

Figure 76.4 Diagram of intraoperative endoscopy of the bile duct distal to a cyst with debris and protein plug. If the distal common bile duct is resected along the red line, over time, a cyst will reform around the distal duct left within the pancreas, leading to recurrent pancreatitis, stone formation, in the residual cyst, or malignant changes in the residual cyst. In contrast, if the distal duct is resected along the blue line, that is, just above the pancreaticobiliary ductal junction, cyst reformation due to residual duct within the pancreas is unlikely. site; if an end-to-side anastomosis is performed far from the closed end of the blind pouch, elongation of the blind pouch will occur later in life as the child grows.

The authors have seldom performed other procedures such as HE at the hilum or valved jejunal interposition hepaticoduodenostomy to prevent reflux of digested food into the IHBD.[39] Although these procedures are appealing theoretically, there is no significant difference in morbidity. HE at the hepatic hilum is more difficult than conventional HE, particularly in neonates and infants without IHBD dilatation, and valved jejunal interposition hepaticoduodenostomy is a complicated procedure.

ASSOCIATED ANOMALIES REQUIRING TREATMENT

IBD dilatation

Recently, more attention has been paid to the treatment of IHBD anomalies such as dilatation with downstream stenosis, which is strongly associated with late postoperative complications.[32,39,51–57] In our series,[13] 8 of 21 neonatal patients (38.1%) had IHBD dilatation (in one, it was severe and was still persistent at follow-up 14 years later), which is remarkably less than the incidence in older children (53.3%).[51] IHBD dilatation can be treated by segmentectomy of the liver, intrahepatic cystoenterostomy, or balloon dilatation of the stenosis at the time of CE.[32,54,55] The authors have treated stricture of the IHBD at the hepatic hilum by

intrahepatic ductoplasty and cystojejunostomy or hepaticojejunostomy at the hepatic hilum in three cases,[51,56] creating a wide stoma by incising along the lateral wall of the hepatic ducts following excision of the narrowed segment of the common hepatic duct (Figure 76.5). By using intraoperative endoscopy, the ideal level of resection of the common hepatic duct can be safely determined without injuring the orifices of the hepatic duct or leaving a redundant duct.

Anomalies of the pancreatic duct and common channel

Anomalies of the pancreatic duct and common channel can include pathology such as stenosis of the papilla of Vater, stricture of the pancreatic ducts, protein plugs, or even a septate common channel.[33,57–59] Stone debris in the common channel and IHBD can also be responsible for postoperative abdominal pain, pancreatitis, stone formation, or jaundice and should be removed at the time of radical surgery. The authors have found intraoperative endoscopic examination of the common channel and intrahepatic duct to be of enough value to include it as a routine procedure during standard surgical treatment of CBD, because it is extremely efficient for examination and irrigation, and allows all distal pancreatic duct stone debris and stone debris in the common channel to be removed. If stenosis of the major papilla with a dilated common channel is found, a transduodenal papilloplasty or endoscopic papilloplasty should be performed.[57]

INTRAOPERATIVE ENDOSCOPY

Since 1986, the authors have routinely performed intraoperative endoscopy of the common channel, pancreatic duct, and IHBD to examine the duct system directly for stone debris and duct stenosis, and to remove stone debris by irrigation with normal saline (Figure 76.8).[51] The authors use a pediatric cystoscope or fine fiberscope with a flush channel to view the pancreatic and biliary duct systems directly at the time of CE.[56,57] In other cases, a neonatal cystoscope, a fine flexible scope (1.9–2.0 mm) with a flush channel, is required. Recently, we found there was a high incidence of IHBD debris not detected by preoperative radiographic investigations,[60] and there were some cases where IHBD debris identified on preoperative radiography was overlooked when the case was reviewed retrospectively. These facts indicate that intraoperative endoscopy is necessary at the time of CE even if preoperative radiography does not indicate the presence of IHBD debris. Another striking finding was that debris can be present in the absence of IHBD dilatation, although debris was more common when the IHBD was dilated. Thus, we believe that inspection using intraoperative endoscopy is mandatory even when there is no IHBD dilatation. In a recent review of the long-term follow-up of our intraoperative endoscopy patients, the incidence of postoperative stone formation was lower than reported in the literature,[61] evidence of the clinical benefit of performing intraoperative endoscopy during CE.

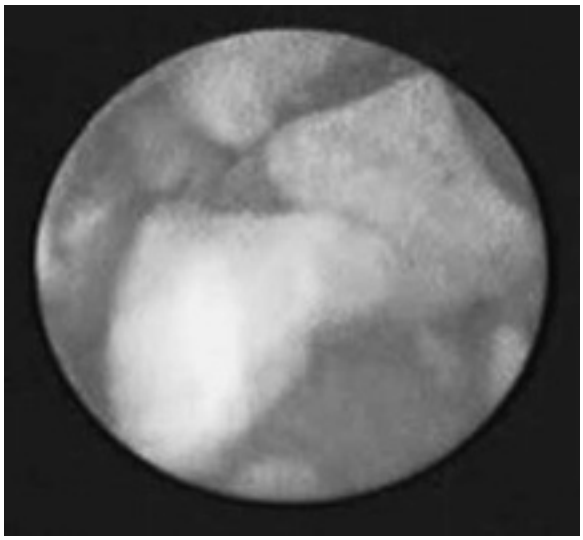

Figure 76.8 Massive debris in the common channel observed through the pediatric cystoscope.

LAPAROSCOPIC SURGERY

Recent advances in laparoscopy technology have enabled pediatric/hepatobiliary surgeons to perform minimally invasive surgery for CBD.[62] In 1995, the first laparoscopic CE in a child was reported.[63] Since then, several authors have reported the safety and feasibility of using minimally invasive techniques for advanced hepatobiliary surgery in children.[64–67] Although technically more challenging, the general concepts are the same as for open surgery. The authors' approach is to use conventionally placed trocars (right upper quadrant, left paraumbilical, left upper quadrant; scope in the umbilicus) to free the cyst and transect it at mid level. An additional 3.9 mm trocar in the left epigastrium is used for a fine ureteroscope for intralaparoscopic endoscopy, similar to intraoperative endoscopy during open CE. Under laparoscope guidance, the tip of the scope is inserted into the common channel through the distal cyst to remove any protein plugs (Figure 76.9).[68] The exact level of transection of the distal common bile duct can also be determined through intralaparoscopic endoscopy,[69] if the orifice of the pancreatic duct in the common channel is identified. After the cyst is freed, the distal part is divided as close as possible to the pancreaticobiliary junction, and the stump is ligated with an ENDOLOOP. When intralaparoscopic endoscopy cannot be performed because of a narrow opening into the intrapancreatic choledochus and common channel (common in cystic CBD), intralaparoscopic cholangiography may be performed by placing an endoscopic metal clip at the distal end of the dissected cyst to confirm the required extent of further dissection distally since the clip and the confluence between the common channel,

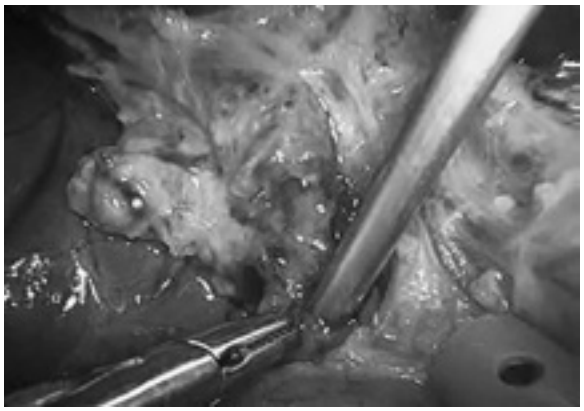

Figure 76.9 Under laparoscope guidance, the tip of the scope is inserted into the common channel through the distal cyst to remove any protein plugs.

intrapancreatic choledochus, and pancreatic duct can be visualized. If dissection is inadequate, the cyst can be further dissected distally and intralaparoscopic cholangiography repeated as previously until cyst dissection is adequate. The proximal cyst is excised leaving 5 mm of common hepatic bile duct. Another two trocars are added for the hepaticojejunostomy: lateral right subcostal, and between the lateral right subcostal and right upper quadrant trocars. Hepaticojejunostomy is performed using interrupted 5/0 or 6/0 absorbable sutures with the right upper quadrant port as a needle holder in the right hand, the 5 mm port for the scope, and the 3 mm subcostal port as a needle receiver in the left hand. Both the right and left edge sutures are exteriorized and used as traction sutures during anastomosis of the anterior wall to facilitate accuracy (Figure 76.10). From our experience, if hepaticojejunostomy is performed without extra trocars, the quality of the anastomosis deteriorates, especially when the diameter of the hepaticojejunostomy anastomosis is <9 mm.

Midterm to long-term follow-up results have been recently published,[70,71] and they found that experienced laparoscopic surgeons would appear to obtain results as good as those for open surgery. In a report comparing laparoscopic CE with open surgery in children [72–75] the operating time was found to be longer, and overall costs higher, but there was significantly less blood loss, and duration of hospitalization was shorter. There were no significant differences for the incidence of bile leakage or wound infection rates. This would appear to suggest that in the hands of skilled laparoscopic surgeons, laparoscopic CE and Roux-en-Y reconstruction are safe and effective.[74–76] Most recently, robot-assisted laparoscopic resection of CBD has been reported.[77,78]

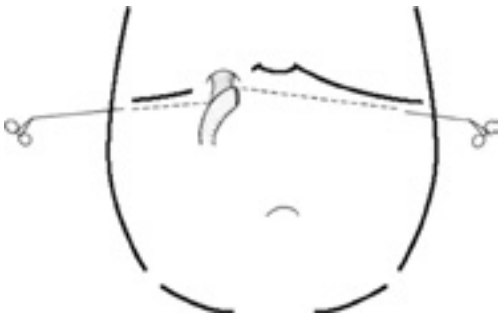

Figure 76.10 Traction sutures facilitate accurate hepaticojejunostomy.

POSTOPERATIVE COMPLICATIONS AND MANAGEMENT

Surgical outcome is better and early morbidity lower in younger children than in older children. The authors[79] reviewed 200 children and 40 adults who underwent CE and hepaticoenterostomy (CEHE) and found that 18 out of 200 (9.0%) children developed complications post-CEHE. No stone formation was seen in the 145 children who had CEHE before the age of 5 years in our series, and there were 18 children who had 25 episodes of complications post-CEHE, including cholangitis, IHBD stone formation, pancreatitis, stone formation in the intrapancreatic terminal choledochus or pancreatic duct, and bowel obstruction. There were no complications in the 70 children who had intraoperative endoscopy in our series. Stones developed in 7 (12.7%) of 55 children who had CEHE when they were more than 5 years old. For management of complications, reoperation was required in 15 children—revision of HE in 4, percutaneous transhepatic cholangioscopic lithotomy in 1, excision of intrapancreatic terminal choledochus in 2, endoscopic sphincterotomy of the papilla of Vater in 1, pancreaticojejunostomy in 1, and laparotomy for bowel obstruction in 6.

Careful long-term follow-up is required, particularly in patients with IHBD dilatation and also dilatation of the remaining distal bile duct, pancreatic duct, and common channel, because there is a risk for chronic inflammation, stone formation, as well as the possibility of carcinoma arising at a later stage.

Hepatic cysts and abscesses

JONATHAN P. ROACH, DAVID A. PARTRICK, AND FREDERICK M. KARRER

INTRODUCTION

Cysts and abscesses of the liver in the neonatal period are uncommon. Hepatic cysts presenting in infants are usually simple, unilocular cysts, with polycystic liver diseases presenting later in childhood or in adults. Most abscesses in infants are pyogenic, with parasitic infections occurring in older children or adults. Cross-sectional imaging studies (ultrasound, computed tomography [CT], magnetic resonance imaging) can typically make workup and localization relatively straightforward. Antenatal diagnosis of liver cysts is now more common with improving scanning technology. Treatment, however, still requires experience and judgment to prevent recurrences or complications.

SIMPLE HEPATIC CYST

Simple or solitary cysts in infants can be congenital or acquired in origin. Parasitic cysts (from hydatid disease) are rare in children and have never been reported in infancy.

Congenital cysts probably arise from defective fusion or obstruction of intrahepatic bile ducts during development, or possibly originate from peribiliary glands.[1,2] These cysts are usually single and unilocular, but septation has been reported.[3] Although one or two thin septa are regarded as normal for a simple cyst, more septae should prompt consideration of other pathologies. Simple cysts are well encapsulated with a smooth surface. There is a 2:1 female preponderance.[4] Most common in the right lobe, they abut or hang down from the liver edge.[3] The liver almost never completely covers the cyst, especially the pedunculated cysts, so the presenting portion has a bluish hue. The internal cyst wall is lined by simple cuboidal or columnar epithelium.[4] Most contain clear fluid, but it may be brownish because of remote hemorrhage. Bilious cyst fluid indicates communication with a biliary radical.

Acquired or posttraumatic cysts may result from blunt trauma or birth trauma, causing an intrahepatic hematoma. The hematoma reabsorbs, leaving behind a cyst cavity. These cysts are lined by granulation tissue and fibrosis and rarely communicate with the biliary tree.

Differential diagnosis of complex cystic structures in the liver

Cystic structures in the neonatal liver also include ciliated hepatic foregut cysts, choledochal cysts, mesenchymal hamartomas (MHs), and cystadenomas.[2,4,5,6] Simple, ciliated, and choledochal cysts usually are unilocular, whereas MH and cystadenomas are multilocular. Ciliated hepatic foregut cysts (CHFCs) are rare cystic structures in the neonatal liver thought to originate from remnants of embryonic foregut buds that are trapped in the liver during development. They are most often seen in the left lobe of the liver. Common imaging characteristics of CHFC are unilocular or bilocular, sediment-containing cysts with calcifications in the cyst wall. Fine needle aspirate of the cyst will show ciliated columnar epithelial cells in a mucoid background.[4] MH is an uncommon tumor of the liver usually presenting before 2 years of age. Characteristic findings in MH are cysts of different sizes, with a variable solid component to the mass. MH may thus be cystic, solid, or mixed in presentation. Although MH is pathologically benign, reports of malignant generation of angiosarcoma and progression to an aggressive clinical course have been described.[6] Complex cysts should be completely excised because of the reported risk of malignant degeneration of these structures.[2]

Choledochal cysts are described in a separate chapter of this textbook.

Presentation

Most congenital cysts do not have any clinical manifestations in infancy and are not diagnosed until an older age (fourth or fifth decade of life). Some are discovered prenatally or incidentally during workup of unrelated problems.[4]

When they are symptomatic in infancy, it is usually because of a visible or palpable upper abdominal mass.[5–8] They rarely cause symptoms from compression of other structures, but infants can present with abdominal distension, feeding difficulties, respiratory distress, and duodenal obstruction secondary to a large cyst.[2] Hemorrhage, secondary infection, rupture or torsion can lead to an acute abdominal condition, but such complications are extremely rare.[9]

Diagnosis

Cysts large enough to be detected on physical exam are easily distinguished from solid tumors by ultrasonography. Liver function is typically normal in spite of the impressive size of these cysts. Plain radiographs may show diaphragmatic elevation or a soft tissue mass displacing the gas pattern in the abdomen. CT is useful to identify the exact location and number of cysts. Other preoperative imaging techniques (cholangiography, angiography, nuclear scans) may provide additional information but are usually unnecessary. With improving imaging technology, many hepatic cysts are being discovered antenatally. In some series, small asymptomatic simple cysts comprised the majority of the prenatal hepatic findings, and these regressed spontaneously. Only one in seven required postnatal surgery secondary to increasing size or symptoms.[2] On prenatal ultrasound, placental pathology in conjunction with hepatic cysts has been linked to MH.[10] If such a finding is noted prenatally, early resection of the liver cyst should be considered.

Treatment

Small asymptomatic cysts (<5 cm) discovered incidentally should be left alone. Large or symptomatic cysts should be treated surgically. Percutaneous cyst aspiration may rule out biliary communication or abscess, but is not definitive therapy because of a high recurrence rate.[11,12] Complete resection is optimal and can be accomplished easily when the cyst is pedunculated.[13] Many of these may be amendable to minimally invasive surgical techniques. If complete excision cannot be accomplished by simple enucleation, formal lobectomy is not typically indicated. These are benign lesions; therefore, the risk of treatment should not exceed the risk of the disease. Under these circumstances, partial excision is preferred. By unroofing at least one-third of the cyst cavity, any serous drainage will be reabsorbed by the peritoneal cavity.[14] The edges of the cyst can be managed by oversewing with a running absorbable suture or by electrocautery. If the cyst contains bile and cholangiography confirms communication of the cyst with the biliary tree, then internal drainage via Roux-en-Y cystojejunostomy is indicated. Infected cysts should be drained externally (see below).

Prognosis

The prognosis for infants with simple hepatic cysts is excellent. Mortality and cyst recurrence should approach zero.[10,15,16,17]

POLYCYSTIC LIVER DISEASE

When liver cysts develop throughout the liver in high number, it is usually in association with an inherited polycystic disease. The two main variants of polycystic disease are autosomal dominant (adult type) and autosomal recessive (childhood type).[18] Both are associated with polycystic disease of the kidney. Autosomal dominant polycystic kidney disease (ADPKD) is the most common form (90%). Symptoms of renal involvement (pain, hypertension, renal failure, urinary tract infection) usually don't develop until adulthood. Liver cysts in autosomal dominant polycystic disease are exceptionally rare in childhood and have not been seen in infancy.

Autosomal recessive polycystic kidney disease (ARPKD) presents in childhood. There are four subgroups (perinatal, neonatal, infantile, juvenile), with varying degrees of involvement of the kidneys and liver.[19] The most severe cases present perinatally with oligohydramnios, Potter's syndrome, and pulmonary hypoplasia and usually die shortly after birth. Patients with lesser degrees of renal involvement present at an older age with renal failure and hypertension. In some children, renal involvement is minor, and they don't present until adolescence with symptoms of portal hypertension such as varicella bleeding.[20]

In all forms of ARPKD, the liver is not usually grossly cystic. The liver abnormality is termed congenital hepatic fibrosis. Microscopically, there is bile duct proliferation with irregular broad bands of fibrous tissue containing multiple microscopic cysts formed by disordered terminal bile ducts, chiefly in the portal areas. The incidence of portal hypertension in ARPKD increases with longevity and appears to be inversely related to the severity of the renal disease. Treatment for portal hypertension is not required in infancy since it takes time for esophageal varices with the tendency to bleed to develop. If portal hypertension leads to esophageal bleeding, endoscopic treatment or portosystemic shunting is preferred. Hepatic synthetic function is usually preserved and the portal hypertension may improve in adolescence as other collaterals develop. Therefore, liver transplantation is usually not needed. Rarely, fibrosis is accompanied by cystic dilation of intrahepatic biliary ducts like Carole's disease. This rare variant does not require treatment in infancy.[21]

The named subgroups of ARPKD aid discussion but are far from distinct. There is, in fact, considerable overlap among individuals and within families. In infancy, the treatment of ARPD only addresses the renal and consequent pulmonary insufficiency. No treatment is required for the hepatic lesion.

HEPATIC ABSCESSES

Incidence and etiology

The most common source of hepatic abscess in children has historically been perforated appendicitis (Figure 77.1),

Figure 77.1 CT abdomen of a 12-year-old girl with a post-appendicitis right lobe liver abscess.

but the incidence in this population has decreased since the introduction of antibiotics. It is now more commonly seen in children with an underlying immune deficiency.[22] Although approximately 50% of children with pyogenic hepatic abscess are less than 6 years old, neonatal hepatic abscesses are rare. One study reported only 3 cases of hepatic abscesses out of 11,403 neonatal admissions.[23] Even though rare, they can definitely be lethal in this vulnerable population. In this review, only 18 neonatal cases of solitary hepatic abscess were identified in the English literature from 1900.[23] In an earlier review, 24 cases were identified historically (including cases of multiple abscesses) to which the authors added an additional 13.[24] Neonatal liver abscess seems to differ considerably from the disease in older children. The patent umbilical vein in neonates provides ready access for bacteria to the liver, and umbilical vessel catheterization is a significant predisposing factor in hepatic abscess formation.[25,26] In hospitalized infants, umbilical vein catheters allow bacteria colonizing the umbilical stump a direct route to the liver. Less common sources of liver abscesses are inoculation via the portal vein from necrotizing enterocolitis,[27] isolated bowel perforations, direct extension from surrounding structures,[25] and other intra-abdominal infections of the newborn. Bacteremia from meningitis or another septic insult can also result in hepatic abscesses via the hepatic artery.[28] Multiple pyogenic hepatic abscesses can complicate neonatal sepsis. Hepatic abscess has also been reported as a rare complication of ventriculoperitoneal shunts (six cases have been reported in the literature, primarily in older patients).[29] More recently, the majority of neonatal cases of hepatic abscess have occurred in premature neonates who are relatively immunosuppressed and have undergone umbilical vessel catheterization (Table 77.1).[21,30] There are reported associations of hepatic abscesses in infants exposed to HIV from the mother, misplaced umbilical catheters (right-sided abscesses), or the use of hypertonic glucose solutions via an umbilical catheter.[30]

Table 77.1 Predisposing factors for neonatal hepatic abscess

Prematurity (immunocompromised)
Umbilical vein catheterization (colonizing organisms, hypertonic glucose solution, misplaced catheter)
Omphalitis
Intra-abdominal infection (necrotizing enterocolitis, bowel perforation)
Bacteremia (meningitis)

The infecting organisms in neonates are more often Gram-negative than Gram-positive. Kays[31] reviewed the infectious causes of pyogenic liver abscesses, and in 22 neonates (<1 month of age), Gram-positive aerobes accounted for only 27% of abscesses, whereas Gram-negative aerobes were responsible for 73%. Fungus was the infectious source in 5% (one patient, although an additional case has since been reported),[21] and anaerobic organisms have not been isolated from any neonatal liver abscess reported in the literature. This is in contrast to older children with hepatic abscess, where up to 50% of infecting organisms isolated are Gram-positive, 25% are Gram-negative, 10% are anaerobic, 6% are fungus, and the remainder are unknown (cryptogenic). Others have noted polymicrobial infections in up to 50% of hepatic abscesses.[32]

Presentation and diagnosis

The clinical diagnosis of neonatal hepatic abscess remains difficult. The classic findings of fever, hepatomegaly, and right-upper-quadrant pain are seldom obvious in the neonate. Signs and symptoms of sepsis may be present, but many infants are simply noted to be irritable, with only mild abdominal distention or tenderness. A rapidly enlarging and tender liver is characteristic for a hepatic abscess, but this is not commonly found on clinical examination. Fever, leukocytosis, and elevation of the sedimentation rate as well as the C-reactive protein may be present. In the majority of patients, liver function tests are normal, but direct and indirect hyperbilirubinemia, elevation of the alkaline phosphatase, elevation of serum transaminase, anemia, and hypoalbuminemia have all been reported.[20] Therefore, to make the diagnosis in neonates, a high index of suspicion is necessary in conjunction with appropriate imaging techniques.

Radiographic evaluation

Plain films may suggest the diagnosis of hepatic abscess by the presence of an elevated right hemidiaphragm and right pleural effusion. Sometimes, a gas shadow can be visualized in the liver itself corresponding to the abscess cavity. Improvements in abdominal ultrasound and CT scanning

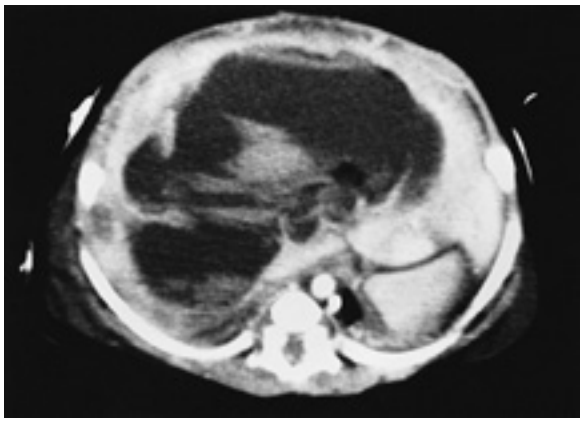

Figure 77.2 CT scan of a large hepatic abscess in a 5-day-old neonate.

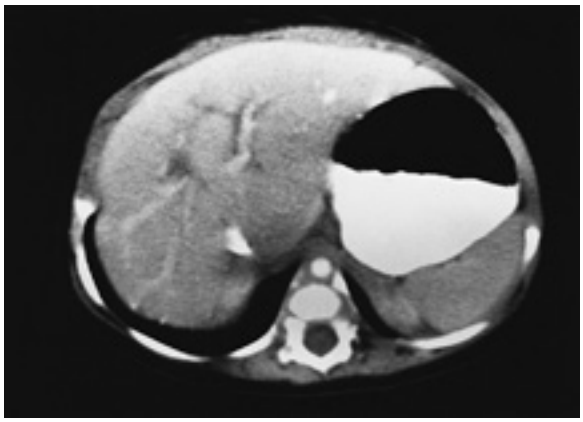

Figure 77.3 Repeat CT scan 6 weeks following open surgical drainage and intravenous antibiotic treatment demonstrating complete radiographic resolution of the hepatic abscess.

now allow for a more rapid and accurate diagnosis in neonates.[33] Ultrasound has the advantage of lower cost, no radiation exposure, relative convenience, and ease of repeating the exam (no sedation, portable).[34,35] A hepatic abscess typically shows low or variable echogenicity by ultrasound, and cystic lesions as small as 1 cm can be identified separate from liver parenchyma. A pyogenic abscess may have more irregular margins on ultrasound compared with an amoebic liver abscess, which may be round and well-defined.[36] CT scanning has demonstrated increased sensitivity compared with ultrasound, and it gives a clearer definition of the abscess.[20] The abscess margins are variably enhanced with the use of intravenous (IV) contrast. Figure 77.2 demonstrates the appearance on CT scan of a large hepatic abscess in a 5-day-old full-term baby. This neonate had an umbilical venous catheter in place with progressive hepatomegaly on physical examination. Included in the differential diagnosis of this cystic mass were hepatoblastoma, infantile hemangioendothelioma, MH, and other rare liver tumors. Any neonate with persistent fever and suggestion of upper abdominal tenderness or an enlarged liver should undergo radiographic examination, especially if risk factors are present. If the ultrasound appears normal but clinical suspicion remains high, CT scanning should be performed. Specific diagnosis requires aspiration of the lesion with Gram stain and culture, leading to subsequent identification of the infecting organism.

Treatment

Systemic antibiotic therapy remains the mainstay of therapy for neonatal hepatic abscess. Initial antibiotic treatment should be started aggressively and include broad coverage. In neonates, empiric treatment should specifically be directed against Gram-negative bacilli and *Staphylococcus aureus*, although anaerobic abscesses have been reported and specific antibiotics covering anaerobes should be considered if the patient does not respond to initial therapy. After cultures identify the infecting organism, antibiotics can be narrowed according to the reported sensitivities. Percutaneous aspiration of smaller neonatal hepatic abscesses can be done for diagnostic purposes,[37] but larger abscesses require therapeutic drainage of the purulent fluid collection for adequate treatment.[38] Percutaneous drainage techniques have been demonstrated to be safe and efficacious in children with hepatic abscesses,[39] and recent experience in neonates has shown similar good results.[21,40] If indicated, an open abdominal exploration allows investigation and possible treatment of an intra-abdominal source of the infection. Laparoscopy may have a role in these patients in this regard. The neonate depicted in Figure 77.2 was treated aggressively with open surgical drainage and IV antibiotics (vancomycin to cover coagulase-negative staph species cultured from the abscess cavity). This aggressive treatment resulted in nearly complete resolution of the process documented by CT within 6 weeks (Figure 77.3). Investigators have variably recommended 2 to 3 weeks of drainage with a total antibiotic course of 3 to 6 weeks.

Once drained and treated with antibiotics, follow-up should include serial ultrasound examination. Most cases should have complete resolution, but chronic, partially calcified foci in the abscess site and portal vein thrombosis have been described after treatment.[40] Prevention of hepatic abscesses may not be possible in neonates given the many potential risk factors they may encounter. According to a Cochrane review,[41] there is no evidence to support the use of prophylactic antibiotics for umbilical vein catheterization to prevent sepsis or liver abscess.

AMOEBIC LIVER ABSCESS

The parasite *Entamoeba histolytica* is generally considered a possible causative organism in older children with hepatic abscess,[42,43] but it has rarely been documented to occur in newborns.[44] Hepatic abscesses due to *E. histolytica* usually follow a 1- to 2-month course of amoebic dysentery.[36] Due to nonspecific signs and symptoms, the diagnosis again rests on clinical suspicion. Serologic testing via indirect

hemagglutination or complement fixation assays can be a useful diagnostic tool. Even though investigators have tried to differentiate the radiographic appearance of amoebic versus pyogenic liver abscesses,[36,45] fine needle aspiration of the abscess cavity is typically required. Return of characteristic "anchovy paste"–appearing material is suggestive of amoebic infection. Presence of trophozoites in stool and positive amoebic serology confirm the diagnosis.[36] Though surgical drainage has been described,[46] amoebic liver abscesses can often be treated successfully with metronidazole and iodoquinal over a 30-day course.[47,48]

Omphalocele and gastroschisis

STEVEN W. BRUCH AND JACOB C. LANGER

INTRODUCTION

Omphalocele (also known as exomphalos) consists of a central abdominal wall defect that permits herniation of abdominal viscera into a sac made up of a three-layered membrane consisting of peritoneum, Wharton's jelly, and amnion (Figure 78.1) that covers the viscera. Pare provided the first description of an omphalocele in 1634. Hey reported the successful treatment of an omphalocele by primary repair in 1803, and Ahlfeld described the escharotic treatment using alcohol in 1899. In 1814, Scarpa observed that omphaloceles were often associated with other congenital anomalies.

Gastroschisis is a smaller abdominal wall defect to the right of a normally positioned umbilical cord, which permits herniation of the intestine (Figure 78.2), as well as occasionally, the liver, testis, or ovary. There is never an associated sac, and other than nonrotation and intestinal atresia, there are few associated congenital anomalies. Gastroschisis was first described by Calder in 1733, and the first surgical treatment for gastroschisis was described by Fear in 1878.

The surgical repair of abdominal wall defects has evolved over many years, with advances in diagnostic ability, neonatal intensive care, and anesthetic techniques. Although Gross popularized the skin flap closure of large omphaloceles in 1948,[1] it was Olshausen who first described this technique in 1887.[2] In 1966, Izant introduced manual stretching of the abdominal wall to make more room for primary closure.[3] Schuster[4] created the first mesh silo in 1967 to temporarily house the herniated viscera until primary closure could be accomplished. Recently, a spring-loaded silo was developed that permits placement of the silo without the need for fascial sutures.[5]

Two additional advances in the medical management of infants with abdominal wall defects have had a significant impact over the past 30 years. Raffensperger and Jona[6] were the first to use postoperative paralysis and ventilator support in the neonatal intensive care unit (NICU) to hasten abdominal wall closure, either primarily or after silo placement.[6] Filler introduced the use of total parenteral nutrition (TPN) to the neonatal population, which has become a crucial component in the high survival rate of infants with abdominal wall defects.[7]

EMBRYOLOGY AND ETIOLOGY

During the sixth week of embryonic development, the intestines begin to grow rapidly and migrate out of the umbilical ring into the umbilical cord.[8] By the 10th week, the intestines return to the abdominal cavity, rotating 270° counterclockwise to attain their normal position. An omphalocele results from failure of the bowel to return to the abdomen, possibly due to delayed closure of the lateral folds with persistence of a large umbilical ring. The defect is centrally located on the abdomen, varies in size, and has a sac covering the abdominal contents that consists of peritoneum, Wharton's jelly, and amnion. Because the process of intestinal rotation normally occurs after return of the viscera to the abdomen, infants with omphalocele usually have nonrotation or malrotation. In addition to the intestine, some or all of the liver may also be present in the sac. The liver is often round and globular in appearance and central in location, and has an abnormal fixation to the diaphragm. The hepatic veins appear tortuous and wander close to the skin edge at the superior aspect of the defect. The spleen and ovaries or testes may also be found in the sac. Failure of the cephalic fold to close leads to lower sternal abnormalities and an epigastric omphalocele, which is commonly associated with cardiac defects, pericardial absence, and an anterior diaphragmatic defect, together known as the pentalogy of Cantrell. Failure of the caudal fold to close leads to a hypogastric omphalocele often associated with bladder or cloacal exstrophy.

Gastroschisis results in bowel herniation through a small defect to the right of the normally formed umbilical cord. There are several hypotheses to explain the development of the gastroschisis defect. DeVries[9] in 1980 postulated abnormal involution of the right umbilical vein, and Hoyme, 1 year later, implicated the disruption of the vitelline artery[10] as a cause of gastroschisis. These vascular etiologies are less

Figure 78.1 Omphalocele. The viscera (in this case liver and small bowel) are covered by a sac that is composed of peritoneum, Wharton's jelly, and amnion. The umbilical cord enters the top of the sac.

Figure 78.2 Gastroschisis. The defect is to the right of the umbilical cord, and the entire intestinal tract is exteriorized. There is no sac. The bowel wall and mesentery become thickened and foreshortened.

likely since neither the umbilical vein nor vitelline artery supplies the anterior abdominal wall. In 2007, Feldkamp et al.[11] theorized that defective closure of one or more of the embryonic body wall folds results in the gastroschisis defect. In 2009, Stevenson et al.[12] proposed that failure of the yolk sac and related vitelline structures to be incorporated into the umbilical stalk results in perforation of the abdominal wall that acts as an egress point for the intestine. More recently in 2013, Rittler proposed a defect in the umbilical ring, not the abdominal wall, with the umbilical cord attached abnormally to the left side of the ring, leaving the right side uncovered.[13] The exact mechanism for the development of gastroschisis remains unclear. Despite this, the clinical scenario is well described. The entire intestinal tract is usually eviscerated, floating free in the amniotic cavity without an enveloping sac. The ovary, testis, and liver are less often involved. The intestines may develop a thick inflammatory peel, are foreshortened, and have a thickened mesentery—findings that correlate with functional impairment of motility and nutrient absorption. These changes result from a combination of factors, including contact with the amniotic fluid and constriction at the abdominal wall defect.

The cause of both omphalocele and gastroschisis is unknown. Omphalocele may have a genetic component, as suggested by the high incidence of structural and chromosomal anomalies, including the association with partial trisomy at chromosome 3q,[14] and by the high incidence of omphalocele in several knockout models in mice.[15] Although gastroschisis is thought not to have a genetic component to its origin, Torfs described four gene polymorphisms associated with an increased risk for gastroschisis,[16] and Kohl found a 2.4% familial recurrence rate in gastroschisis.[17]

INCIDENCE

The incidence of gastroschisis has been increasing worldwide over the past two decades. During that same time, the incidence of omphalocele has remained relatively constant, with an incidence of 1.92 per 10,000 live births in the United States.[18] The EUROCAT working group reported that the incidence of gastroschisis increased from 0.60 per 10,000 births in 1980–1984 to 2.33 per 10,000 births in 2000–2002[19] and 3.09 per 10,000 in 2011.[20] From 1987 to 2003, the overall birth prevalence for gastroschisis increased 3.2-fold in a population-based study from California.[21] The reason for this increase in gastroschisis but not in omphalocele is not well understood. Investigators have reviewed the currently available literature on nongenetic risk factors for gastroschisis including sociodemographic factors, maternal therapeutic and nontherapeutic drug exposures, chemical exposures, and other factors.[22,23] They found that the only factor definitively identified as a risk factor for gastroschisis is young maternal age. Other factors that may be associated, but require further confirmation, include ethnicity, socioeconomic status, poor nutrition,[23] cigarette smoking,[22] illicit drugs (including cocaine, methamphetamines, and marijuana),[23] certain medications (including aspirin, pseudoephedrine,[22] and selective serotonin reuptake inhibitors such as Paxil[24]), recent change in paternity, short cohabitation time,[22] gynecologic infections including *Chlamydia*,[25] and increased exposure to estrogens.[26]

ASSOCIATED ANOMALIES

As a rule, it is rare for gastroschisis to be associated with other anomalies, but it is very common for omphalocele.

A European study revealed that only 14% of infants born with omphalocele had no other anomalies. The majority of these infants, up to 88%, will have multiple associated anomalies.[27] Interestingly, small omphaloceles, less than 4 cm in diameter, have a higher incidence of multiple anomalies (55%) compared to giant omphaloceles (36%).[28] These anomalies include chromosomal abnormalities (trisomy 13, 18, and 21 being most common) in 30%–40%, cardiac abnormalities in 14%–47%, central nervous system abnormalities in 3%–33%, and associated syndromes including cloacal exstrophy, pentalogy of Cantrell, Donnai–Barrow syndrome, and Beckwith–Wiedemann syndrome in up to 12%.[27] Giant omphaloceles often develop chest wall and rib abnormalities, resulting in a narrow elongated chest with down-slanting ribs, and pulmonary hypoplasia, resulting in pulmonary insufficiency.[29] Pulmonary hypertension complicates up to 37% of giant omphaloceles, and these pulmonary issues may persist even after repair.[30] Gastroschisis, on the other hand, is usually an isolated lesion. In a review of over 3000 cases of gastroschisis, Mastroiacovo identified 14.1% of cases as nonisolated.[31] The majority of associated anomalies take the form of intestinal atresia; chromosomal abnormalities are rare. Recent Canadian Pediatric Surgery Network (CAPSNet) data broke down the anomalies associated with gastroschisis as follows: intestinal atresia 9.1%, cardiac 2.8%, genitourinary 2.4%, musculoskeletal 1.2%, and central nervous system 0.6%.[32,33] Interestingly, fetuses with gastroschisis and in utero fetal demise had a 10-fold increase in associated anomalies compared to live-born infants who survived greater than 24 hours.[33]

FUNCTION OF EXTERIORIZED VISCERA

Because of the presence of a sac in most omphaloceles, the exteriorized viscera usually function normally. In gastroschisis, the uncovered bowel is exposed to amniotic fluid, and its mesentery is subjected to varying amounts of constriction at the abdominal wall defect. Clinically, this leads to intestinal wall thickening, chronic inflammation, and often, a fibrous peel resulting in impaired motility and nutrient absorption.[34] The intestinal damage arises from exposure to fetal urine and, more importantly, meconium in the amniotic fluid, and from ischemia due to the restricted mesenteric blood flow at the gastroschisis defect.[35,36] These two insults appear to cause independent and additive damage.[37] This damage results in histologic changes in the gastroschisis bowel with increased submucosal collagen deposition and hypertrophy of the smooth muscle layer.[38] In addition, there is evidence of delayed differentiation of both smooth muscle and the Interstitial cells of Cajal in a rat model of gastroschisis.[39] The histopathologic changes along with the alteration in the intestinal nervous system lead to the impaired motility and absorption.[40] Recently, the infusion of mesenchymal stem cells into the amniotic fluid prevented the increase in bowel wall thickness usually seen in a rat gastroschisis model.[41] This may provide bowel protection for gastroschisis in the future.

PRENATAL DIAGNOSIS AND MANAGEMENT

The unique anatomic characteristics of omphalocele and gastroschisis allow them to be identified and differentiated using prenatal ultrasound. The diagnosis of omphalocele cannot be made definitively prior to the 10th gestational week, as the intestines are normally located in the umbilical cord up until that time. Although it is usually possible to sonographically differentiate omphalocele from gastroschisis, prenatal rupture of an omphalocele may make this more difficult. An abdominal wall defect is often suspected on routine screening because of elevation of the maternal serum alpha-fetoprotein (MSAFP), which is elevated in 90% of mothers carrying fetuses with omphalocele and 100% of those with gastroschisis.[42] Using a combination of maternal serum screening and ultrasound, the sensitivity and specificity for prenatal diagnosis of abdominal wall defects should approach 100%.[43]

Once an abdominal wall defect is identified, a search for additional anomalies should be carried out. If the problem is clearly gastroschisis, this can be limited to a careful anatomic ultrasound. The ultrasound exams should be repeated serially, evaluating for changes in the bowel appearance. Rare cases of vanishing gastroschisis occur where the abdominal defect closes and the extruded bowel disappears. The babies are born with an intact abdominal wall and a bowel atresia with significant loss of bowel length. Mechanistically, it is not known if the abdominal defect closes or the bowel loss occurs first, but the result is the same. For fetuses with omphalocele, both structural and chromosomal problems should be sought. Karyotype analysis by amniocentesis or chorionic villous sampling, and an anatomic ultrasound, including fetal echocardiography, should be completed. In most series, approximately two-thirds of associated abnormalities are detected prenatally in fetuses with omphalocele.[44]

Several prenatal indices may help predict neonatal outcome in fetuses with abdominal wall defects. In the case of omphalocele, the observed-to-expected fetal lung volume on magnetic resonance imaging (MRI)[45] and the ratio of omphalocele diameter to abdominal circumference ultrasound[46] have been used to predict such outcomes as primary closure within 24 hours, length of time on the ventilator, time to first and full enteral feeds, and length of neonatal stay. Investigators have studied prenatal ultrasound findings in fetuses with gastroschisis looking for signs that would predict bowel atresia and thus poorer outcomes. A recent meta-analysis revealed that intra-abdominal bowel dilation (odds ratio 5.48) and polyhydramnios (odds ratio 3.76) were risk factors for bowel atresia, whereas extra-abdominal bowel dilation and gastric dilation were not.[47]

At present, there are no intrauterine interventions indicated for fetuses with abdominal wall defects. There was interest in amnioinfusion in the past, theorizing that replacing the amniotic fluid with saline would decrease the concentration of the irritating factors in the fluid. However, amnioinfusion

has not proven effective in reducing the inflammatory status of the amniotic fluid or in improving postnatal outcomes.[48] However, there continues to be controversy over the optimal timing and mode of delivery for infants with abdominal wall defects. Infants with omphalocele should be delivered at term. There is general agreement that infants with a very large omphalocele should be delivered by cesarean section to prevent injury to the exteriorized liver; however, infants with smaller defects should probably be delivered vaginally unless there are obstetric indications for cesarean section.[49] On the other hand, infants with gastroschisis may benefit from early delivery to minimize damage from exposure of the bowel to amniotic fluid, and to avoid late intrauterine fetal demise.[50] A number of investigators have reviewed this controversy, most with case series from one institution that used historical controls. There has been one randomized controlled trial with small numbers (only 20 mothers in each arm) that showed no difference in survival to hospital discharge, or any other neonatal outcome, with planned induction at 36 weeks estimated gestational age (EGA) compared with spontaneous labor.[51] Of interest, both groups had a similar gestational age at birth, suggesting that mothers carrying infants with gastroschisis tend to go into spontaneous preterm labor and deliver early. Barseghyan noted a 43% spontaneous preterm delivery rate with gastroschisis, compared to a 12.8% rate in the general US population, resulting in a mean EGA of 35 4/7 weeks.[52] In addition to this randomized controlled study, a large nationwide database is becoming mature enough to help answer this question. CAPSNet has prospectively collected data on all fetuses with the diagnosis of gastroschisis since 2005. Using these data, Al-Kaff looked at differences in neonatal outcomes depending on the planned route and timing of delivery that was made at 32 weeks EGA. He found no difference in median EGA at delivery (36 weeks) whether the labor was induced or allowed to occur spontaneously. There were also no differences in neonatal outcomes including length of stay, length of TPN required, and time to first enteral feeds. From this, he concluded that there were no major health benefits from planned early delivery.[53] Youssef, using the same database, looked at bowel damage as it relates to time of delivery. He found a 1.4% fetal loss rate, which occurred mostly early in gestation. After evaluating the gastroschisis prognostic score, which stratifies the severity of the gastroschisis bowel abnormalities at birth, and the amount of bowel matting identified at birth, he concluded that there is no indication for early delivery to prevent bowel damage.[48] Again, using the CAPSNet database and looking at the actual timing of delivery, Nasr found that infants born with gastroschisis before 36 weeks EGA had a longer time interval to full enteral feeds and more complications, while those born after 38 weeks EGA had more bowel matting. He suggested that induction of labor between 36 and 38 weeks EGA may reduce gastroschisis-related bowel morbidity while avoiding the risks related to prematurity.[54] Routine cesarean section has shown no benefit compared to vaginal delivery, so the route of delivery should be based on obstetric indications.[48]

NEWBORN MANAGEMENT

The initial treatment of a newborn with an abdominal wall defect consists of resuscitation, including evaluation of the airway and pulmonary status; this is particularly important for infants with giant omphalocele, which may be associated with pulmonary hypoplasia. Intravenous access allows volume resuscitation. In infants with gastroschisis, the bowel should be inspected to ensure that its blood supply is not compromised by twisting of the mesentery or constriction at the abdominal wall defect. If the size of the abdominal wall defect in gastroschisis is causing vascular compromise, the defect should be enlarged immediately. The bowel should be wrapped in warm saline-soaked gauze and covered with a waterproof dressing (Figure 78.3). A bowel bag or cellophane works well for this purpose. Children with gastroschisis should be transported and nursed on their right side to avoid kinking of the mesenteric vessels. In infants with omphalocele, the sac should be inspected for leaks before placing the dressing.

Newborns with abdominal wall defects should be placed in a temperature-controlled environment, as they lose a great deal of heat through the exposed bowel. Babies with gastroschisis require up to 2–3 times the amount of fluid a normal term infant would require. Despite the intact abdominal wall, babies with an omphalocele will have greater fluid and temperature losses than a normal infant, but not to the degree that is seen with gastroschisis.[28] Isotonic solutions should be used for resuscitation, and the child should be well hydrated prior to going to the operating room (OR) for repair. Once fluid resuscitation has been accomplished, parenteral nutrition, preferably through a central venous catheter, should be initiated.

All infants should be carefully examined clinically and radiologically to ensure that adequate pulmonary, cardiac, and renal function are maintained. Associated anomalies must be diligently searched for, particularly in those infants with omphalocele.

Figure 78.3 Appropriate dressing of an abdominal wall defect in the delivery room. The viscera are covered with warm saline-soaked gauze, supported on the anterior abdominal wall and covered with a waterproof dressing.

The appearance of the bowel noted in gastroschisis shortly after birth, within 6 hours, can be predictive of clinical outcome. Cowan developed the Gastroschisis Prognostic Score based on inspection of the exteriorized bowel for bowel matting (none 0, mild 1, severe 4); atresia (absent 0, suspected 1, present 2); perforation (absent 0, present 2); and necrosis (absent 0, present 4). A score of 2 or more is associated with increased complications and prolonged hospitalization, and a score of 4 or more increases the odds of mortality.[55]

SURGICAL MANAGEMENT

The goal of surgical management for abdominal wall defects is to replace the herniated viscera in the abdominal cavity and obtain fascial and skin closure with an acceptable cosmetic outcome. Various issues arise that make the closure strategy different for gastroschisis and omphalocele. The exposed bowel in gastroschisis requires an immediate intervention. Historically, primary closure was the first successful method introduce by Watkins in 1943.[56] Staged silo repair was introduced by Schuster[4] in 1967 and allowed for the survival of many more babies with gastroschisis. The strategy at that time became an attempted primary closure, and if that was not possible, a silo was formed, and a staged reduction was performed followed by operative fascial closure (Figure 78.4). Fischer described the first preformed silo in 1995.[57] and these become popular in the late 1990s (Figure 78.5). This provided an easily placed silo that could be applied in the delivery room, the NICU, or the OR, often without the need for intubation or significant sedation. The treatment pendulum has now swung to where the majority of babies with gastroschisis are treated this way to prevent the development of abdominal compartment syndrome, which can result in ischemic or necrotic bowel, renal insufficiency, and respiratory distress.[58] Chesley reported that at his institution, their practice was to attempt primary closure and use a surgically created silo if necessary before the spring-loaded silos arrived. They achieved a 60% primary closure rate. When the spring-loaded silos became available, their primary closure rate decreased to 15%.[59] Sandler described suture-less closure for gastroschisis in 2004.[60] After intestinal reduction, the umbilical cord is used as a plug and secured in place by a clear adhesive dressing. This allows the umbilical ring to close naturally, forming

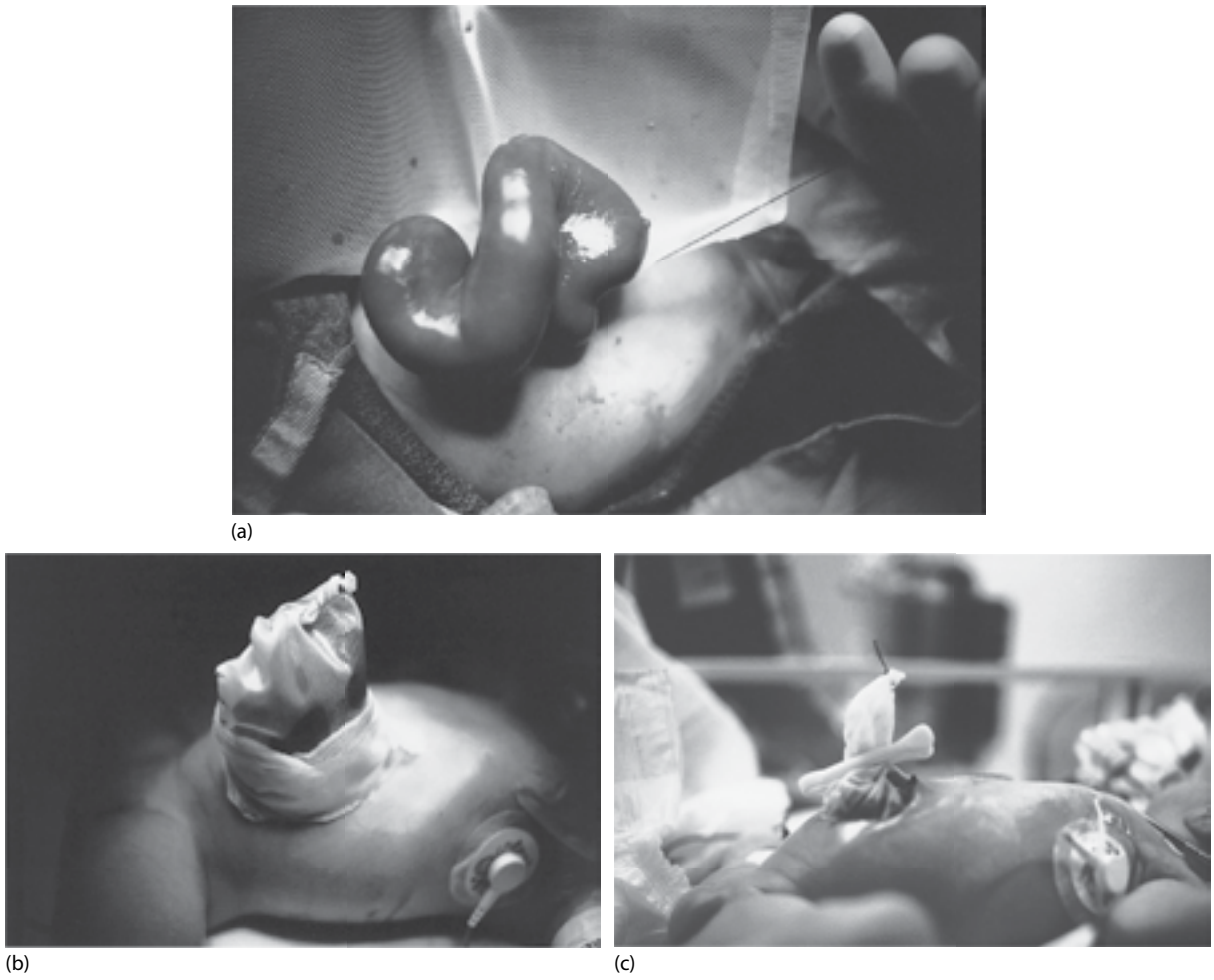

Figure 78.4 The use of a silo in a child with gastroschisis. **(a)** The silo is sewn to the abdominal wall, over the bowel. **(b)** The bowel is slowly reduced once or twice per day. **(c)** The abdominal wall is ready to be definitively closed.

a normal-appearing umbilicus. This technique works even for the large defects resulting from a preformed silo as long as the umbilical ring is not opened,[61] which is reportedly required in 11%–44% of silo placements.[58,62] Following this, Chesley's group[59] again achieved a 60% primary closure rate. Stanger, using the CAPSNet data, reports a successful primary closure rate of 81%.[63] The majority of pediatric surgeons attempt a primary reduction with or without a suture-less closure and use a preformed silo in the event that a primary repair cannot be completed. There are, however, some proponents of an initial preformed silo placement. A randomized trial[64] and several large meta-analyses[65–67] reviewed preformed silo placement and staged closure versus primary repair in gastroschisis and found nearly all clinical outcomes equivalent. The CAPSNet data did make a distinction between successful and failed primary closure and showed that those who failed initial primary closure experienced more surgical site infections and more culture-proven bacteremia, and had a longer duration of parenteral nutrition, later initiation of enteral feeds, and more days of mechanical ventilation.[63]

The approach to the 10% of babies with bowel atresia associated with gastroschisis varies depending on the appearance of the bowel. If the atresia is identified at the time of closure and the bowel inflammation is minimal, a primary anastomosis is favored. If the bowel inflammation makes primary closure impossible, the ends should be reduced, and the abdomen closed with a plan to return in 4–6 weeks for atresia repair. On occasion, the atresia is not recognized at the time of closure. The baby will not have return of bowel function, and contrast studies from above and below will reveal the atresia. Stoma creation can be used, and on occasion, the best place to create the stoma is in the gastroschisis defect at the umbilicus.

The sac that covers the viscera in an omphalocele makes immediate surgical intervention unnecessary unless there is a hole in the sac. Historically, Hey reported the first successful primary closure of an omphalocele in 1805, and in 1948, Gross described the skin flap technique, where skin flaps but not fascia covered the bowel in giant omphaloceles.[1] The surgical strategy employed now for omphalocele is determined by the size of the defect and the physiologic status of the infant. With a small defect, a primary repair is in order. The sac is removed, and the fascia and skin are brought together. With larger defects that cannot be repaired primarily, there are several options. One is to remove the sac and place a silo, usually sewn to the fascia, as the preformed silos have a difficult time staying in the large omphalocele defects. The contents are then gradually reduced into the abdominal cavity. The silo is then removed, and the fascia and skin are closed. Occasionally, the fascia must be left open with skin closure only, or a piece of mesh can be placed either temporarily or permanently to span the fascial defect and allow skin closure. In infants with a giant omphalocele, defined as a defect greater than 5 cm in diameter with at least one-half of the liver being present in the sac, or in infants with poor physiology that would not tolerate increased intra-abdominal pressure, a second option is the "paint and wait" strategy. This involves dressing the omphalocele membrane with an antimicrobial substance, usually silver sulfadiazine, and allowing the membrane to firm up, granulate, and epithelialize, providing pseudo-skin coverage over the sac (Figure 78.6). The use of negative-pressure wound therapy applied in the first 48 hours after birth to the omphalocele sac may allow earlier epithelialization to occur. Wound healing was complete in 2 months with negative pressure compared to the 6 months often required to complete wound healing when using silver sulfadiazine.[68] The infants usually go home for a period of time and return for fascial closure later in life when their pulmonary and cardiac status has improved. On occasion, after epithelialization, there is not enough abdominal domain to allow complete reduction of the viscera in giant omphaloceles. In these situations, tissue expanders have been used to increase the space in the abdominal cavity, allowing reduction of the viscera and final closure.[69] Final closure may be obtained by bringing the fascia together primarily, using mesh, either permanent or biologic,[70] or employing a multilayered flap technique.[71]

There are a few caveats regarding these methods. When attempting primary closure or initial placement of a silo, the sac is often very adherent to the liver, so that it is often best to leave some of the sac behind on the liver to avoid significant bleeding from the attempt to separate the sac from the liver capsule. As the dissection of the sac proceeds cephalad, care should be taken not to injure the hepatic veins, which will be located just under the fascia due to the abnormal position of the liver and the inferior vena cava. The abrupt change in the position of the liver in an attempted primary closure may kink these hepatic veins or the inferior vena cava, causing cardiovascular compromise. If this occurs, the liver should be taken out of the abdomen and placed in a silo. Often, with gradual reduction in a silo, this problem will be circumvented.

Figure 78.6 Escharotic management of a large omphalocele. **(a)** The sac is covered with silver sulfadiazine. This results in the formation of granulation tissue and ultimately in epithelialization. **(b)** The resulting ventral hernia can be repaired at any time, when the child's medical condition improves.

POSTOPERATIVE MANAGEMENT

Postoperatively, feedings are started when gastrointestinal function returns. This usually occurs more quickly in infants with omphalocele compared to gastroschisis and can take weeks to months. A review of the CAPSNet data revealed that in gastroschisis, the elapsed time from abdominal wall closure to the initiation of enteral feeds took a mean time of 17 days.[72] The abnormal intestinal motility and nutrient absorption of the exposed bowel in gastroschisis gradually improve over time but can affect the babies for up to 6–9 months. During the initial wait for bowel function to return, nasogastric decompression with parenteral nutrition sustains the infants. Feeding, or oral stimulation if feeds are not feasible, should be initiated as soon as possible to prevent oral aversion. Earlier initiation of enteral feeds predicted earlier TPN independence, a shorter length of stay, and less infectious complications in a CAPSNet review. This review also revealed a benefit to waiting at least 7 days to initiate feeds.[72] Feedings ,should be advanced cautiously in order to avoid inducing necrotizing enterocolitis which occurs in gastroschisis at a much higher frequency (up to 18.5%) than would be otherwise expected.[28]

Feeding difficulties are much less common following repair of omphalocele since the bowels have been protected by the omphalocele sac and should function normally as long as they are not compromised due to the pressure exerted by the fascial closure. However, pulmonary issues caused by pulmonary hypoplasia and pulmonary hypertension may result in prolonged mechanical ventilation following repair,

Table 78.1 Long-term quality of life

		Gastroschisis	Omphalocele
Gastrointestinal issues	Frequent	7%	10%
	Rarely or never	77%	75%
Physical limitations		9%	7%
Cosmetic results	Good or excellent	82%	73%
	Umbilical reconstruction	23%	35%
	Troubled by lack of umbilicus	24%	11%
Abdominal wall hernia		14%	20%
Delayed sitting or walking		32%	27%
Began school at usual age		77%	93%
Growth	Weight < 3rd percentile	9%	20%
	Height < 3rd percentile	14%	13%

not only in the newborn period but also following delayed repair later in childhood.

LONG-TERM OUTCOME

The outcome of infants born with gastroschisis depends on the condition of the intestine. In uncomplicated cases of gastroschisis, the overall survival is greater than 90%.[73–76] However, infants with gastroschisis that requires home TPN due to loss of bowel length or inability to tolerate enteral feeds despite normal bowel length have a 50% mortality rate in the first 2 years of life.[76] A significant number of these patients require additional surgery, usually for adhesive intestinal obstruction, and a small group of children suffer from short bowel syndrome or long-term motility disorders, which ultimately require small bowel transplantation.[77] In fact, gastroschisis is the most frequent indication for pediatric small bowel transplantation.[78] The outcome for infants with omphalocele is more dependent on the presence and severity of associated malformations. In the absence of chromosomal abnormalities, or severe pulmonary or cardiac anomalies, the majority of these children survive to live normal lives.[73,74] Henrich et al.[79] looked at several aspects of long-term quality of life in children with gastroschisis and omphalocele. These are depicted in Table 78.1. The results are similar in the two groups and reveal a satisfying overall quality of life for these children after long-term follow-up. The long-term neurodevelopmental outcomes of school-aged children and adolescents born with gastroschisis revealed overall normal intellect with a small but significant decrease in working memory index compared to normal children. There were no children with cerebral palsy or significant visual or hearing deficits noted in this group.[80]

Omphalomesenteric duct remnants

KENNETH K. Y. WONG AND PAUL K. H. TAM

INTRODUCTION

The omphalomesenteric duct or the vitelline duct is a long narrow tube that joins the yolk sac to the digestive tube in the developing human embryo. This duct undergoes complete obliteration during the seventh week in most cases. However, in the rare circumstances where there is incomplete obliteration, omphalomesenteric remnants will be the result, which may be apparent in the newborn infant.[1]

ETIOLOGY

Development of the midgut in the embryo is characterized by growth and elongation of the gut at the end of the fourth week of gestation. At the apex, the intestinal loop remains connected and open to the yolk sac via the omphalomesenteric duct.[2] In some neonates, this duct persists due to incomplete obliteration and resorption (unknown cause), thus giving rise to the various anatomical anomalies as described in the next section.

PATHOLOGY

Omphalomesenteric remnants can be classified into various types according to the underlying anomaly (Figure 79.1):

1. Persistent omphalomesenteric duct (patent or obliterated)
2. Omphalomesenteric duct cyst
3. Meckel diverticulum
4. Umbilical mucosal polyp/umbilical cyst

HISTORY, PRESENTATION, AND DIAGNOSIS

Persistent omphalomesenteric duct

The persistent omphalomesenteric duct may remain patent after birth and present as an omphaloileal fistula. The fistula may contain ectopic gastric, colonic, or pancreatic tissue. Affected neonates often present with umbilical discharge, which resembles small bowel content and can result in periumbilical excoriation. An umbilical "polyp" consisting of intestinal mucosa may also be present. The diagnosis is confirmed by passing a catheter through the fistula into the small intestine and aspirating small bowel content, or by injecting radiographic contrast medium into the fistula to perform a "fistulogram."

Rarely, the ileum may even prolapse through the omphaloileal fistula—giving rise to the so-called steer-horn abnormality (Figure 79.2), which may give rise to intestinal obstruction.

For obliterated omphalomesenteric duct, it may persist as a fibrous cord attaching the ileum to the umbilicus internally. The infant who has this anomaly is usually asymptomatic. However, there is a risk of small bowel volvulus occurring around such a band.

Omphalomesenteric duct cyst

The obliterated omphalomesenteric duct may contain one or more cysts. The clinical presentation of this is similar to obliterated duct, with a risk of small bowel volvulus. Sometimes, the cyst can become infected, and the child may present with pain and fever.

Meckel diverticulum

The most common omphalomesenteric remnant seen is the Meckel diverticulum, which is the persistence of the enteral end on the antimesenteric side of the small intestine (Figure 79.3). This anomaly occurs in around 2% of the population, with its location usually within 2 feet of the ileocecal, around 2 inches long, and usually presents below the age of 2 years ("rule of 2s"). Complications of the diverticulum include bleeding, diverticulitis, and intussusception. Asymptomatic ones are usually found incidentally at laparotomies for other conditions. A recent

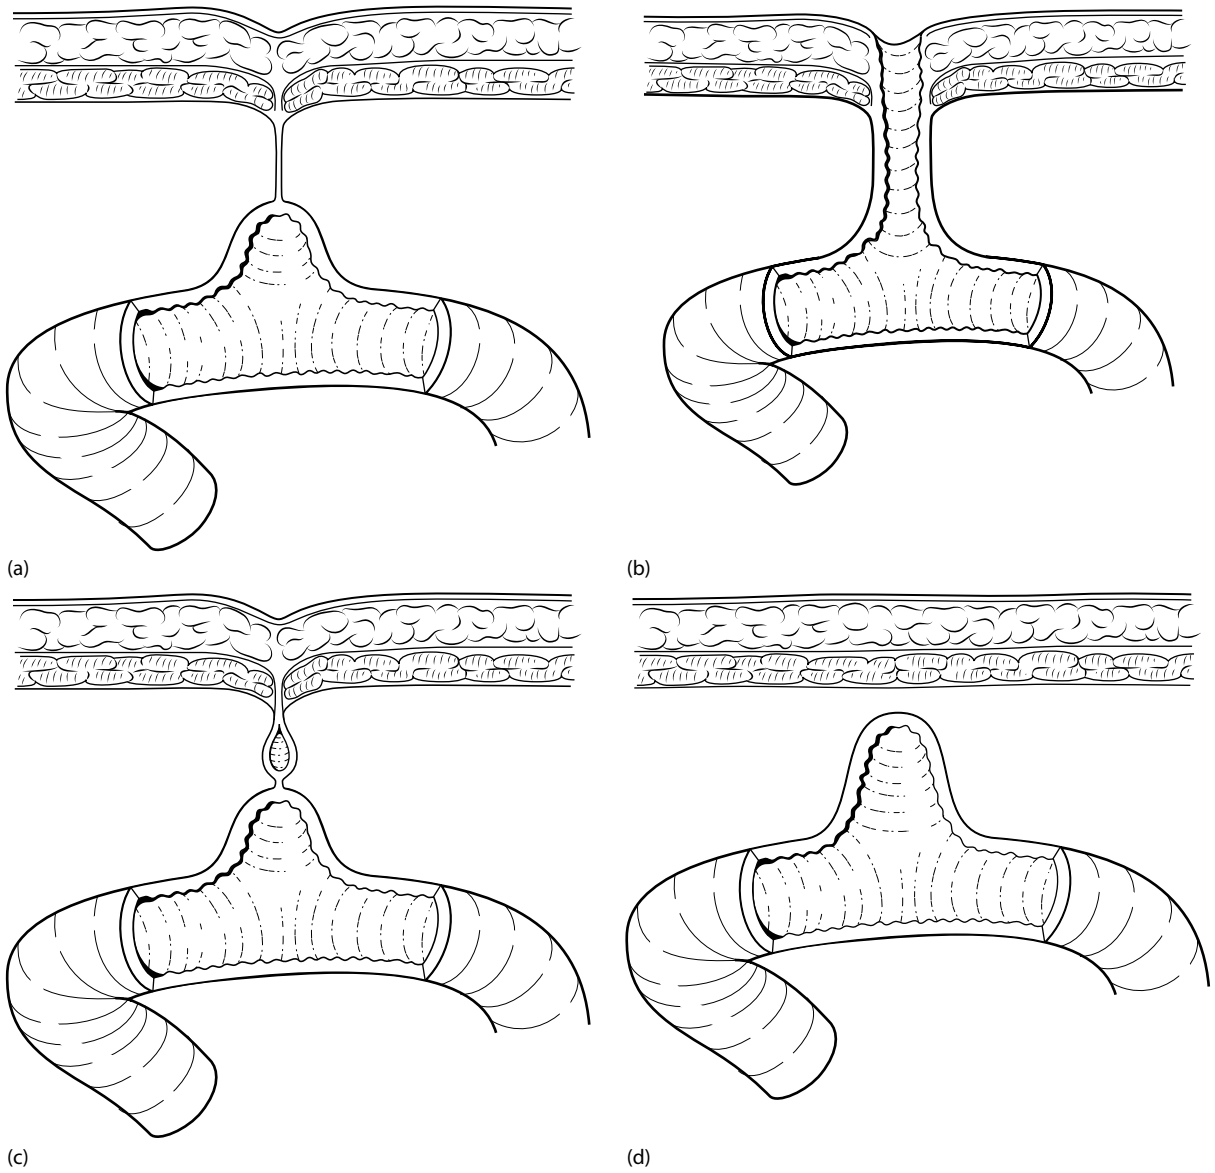

Figure 79.1 Schematic diagrams showing the various anatomical variations of omphalomesenteric remnants. **(a)** Obliterated omphalomesenteric duct. **(b)** Patent omphalomesenteric duct. **(c)** A cyst in an obliterated omphalomesenteric duct. **(d)** Meckel diverticulum.

study showed that resection of incidentally detected Meckel diverticulum had a significantly higher postoperative complication rate than leaving it in situ and that 758 resections would need to be performed to prevent 1 death from the condition. As a result, there is no evidence to support the resection of incidentally detected Meckel diverticulum.[3]

For diagnosis, the presence of ectopic gastric mucosa with the secretion of gastrin can be detected using Tc-99 radioisotope scanning (Figure 79.4), although a negative result does not exclude the presence of Meckel diverticulum (sensitivity of Tc-99 around 80%–85%).[4] In a young infant presenting with significant per rectal bleeding with hemoglobin drop, Meckel diverticulum should be one of the top diagnoses on the list.

Umbilical polyp

An umbilical polyp is a remnant of intestinal mucosa at the umbilicus. The pink, polypoid tissue produces a persistent discharge, which may be bloodstained. The other differential diagnosis is an umbilical granuloma, which should respond to simple cauterization treatment. The diagnosis of an umbilical polyp may be confirmed by biopsy to look for the presence of intestinal or gastric mucosa.

OPERATIVE MANAGEMENT

Omphalomesenteric remnants are best managed operatively,[5] and the approaches for the various anomalies are described as follows.

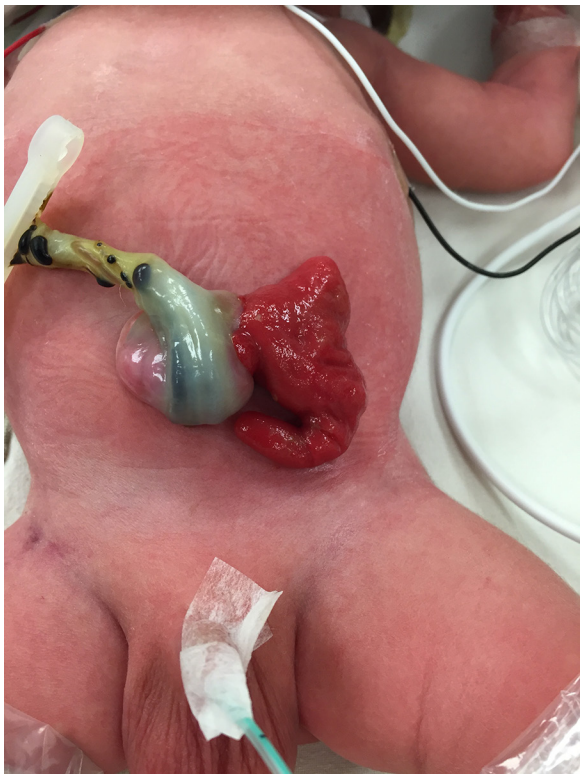

Figure 79.2 A clinical photograph showing an omphaloileal fistula giving rise to the so-called steer-horn abnormality.

Figure 79.3 An intraoperative photograph showing Meckel diverticulum delivered out through an umbilical incision.

Excision of a patent omphalomesenteric duct

The orifice of the fistula is mobilized using a circumferential incision, preserving the surrounding umbilical skin (Figure 79.5). A separate skin-crease incision is made below the umbilicus. The superior skin flap, which includes the umbilicus, is elevated, and the fistula is brought out

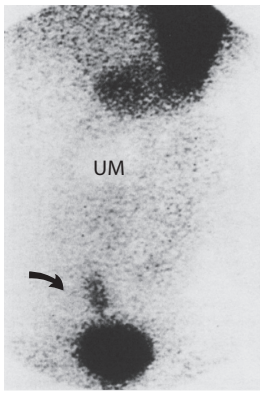

Figure 79.4 A photograph of a Tc-99 radioisotope scan taken at 20 minutes, showing the presence of gastrin-secreting mucosa in a Meckel diverticulum.

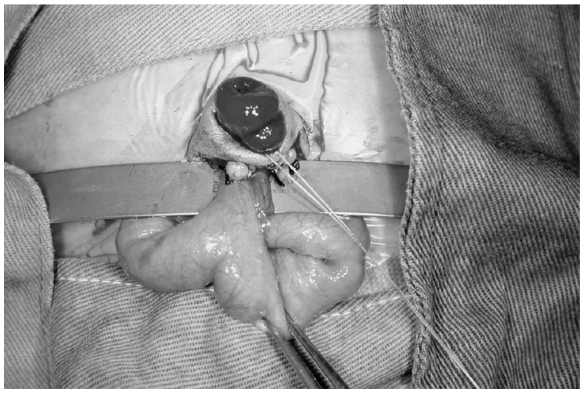

Figure 79.5 An intraoperative photograph taken after dissection of a patent omphalomesenteric duct.

through the subumbilical incision. The abdominal wall fascia is incised transversely on either side of the fistula. The umbilical vessels and the urachus are individually ligated and divided, and the peritoneal cavity is entered. The fistula is traced to its termination on the distal ileum.

The blood supply to the fistula runs across the ileum and should be ligated and divided near its origin on the mesentery. The fistula is excised with a margin of ileum using a transverse elliptical incision. The ileal defect is repaired transversely with a single interrupted layer of absorbable 4-0 sutures. The linea alba is then repaired and the subumbilical incision closed with subcuticular 5-0 suture. The circular defect in the center of the umbilicus may be left to heal by secondary intention if small, or may be loosely closed with a purse-string suture. The healed wound should resemble the umbilicus.

Meckel diverticulectomy

Symptomatic and confirmed Meckel diverticulum should be excised. For those patients who are asymptomatic, it is not essential to remove it. Nowadays, the procedure is laparoscopically assisted (where the Meckel diverticulum is brought through the subumbilical port after extension

of incision to 2 cm) or even performed wholly laparoscopically in many centers. Laparoscopy is also useful in helping to diagnose symptomatic patients with negative isotope scans. The principles of laparoscopic resection remain the same as open surgery, and it is the authors' preference to resect a short segment of ileum together with the diverticulum to ensure that all abnormal mucosa is removed.[6,7] For open surgery, a 2 cm periumbilical incision is used to gain access to the peritoneal cavity. This will ensure an excellent cosmetic result postoperatively.

The Meckel diverticulum is situated on the antimesenteric border of the distal ileum and may be bound to the adjacent small bowel mesentery by a covering of peritoneum. These adhesions are divided to mobilize the diverticulum. Occasionally, the diverticulum is attached to the umbilicus, from which it must be separated. The blood vessels on the mesenteric side are ligated and divided. Ileal resection with primary end-to-end anastomosis with single-layer, interrupted absorbable 4-0 sutures is carried out. This ensures the removal of all ectopic tissue. The fascia of the subumbilical incision is closed using 3-0 absorbable sutures, and the skin is approximated with subcuticular 5-0 suture reinforced with adhesive strips.

Excision of an umbilical polyp

A circumferential incision is made around the polyp, preserving as much of the normal umbilicus as possible. The skin defect is repaired using an absorbable purse-string suture. Because of the possibility of an underlying connection to the ileum by a remnant of the omphalomesenteric duct, limited exploration of the peritoneal cavity is advisable. A subumbilical incision is made as described earlier. The abdominal wall is opened transversely and the peritoneal cavity entered. If an omphalomesenteric duct remnant is present, it is resected.

COMPLICATIONS

For conditions that involve peritoneal access (either open or laparoscopic) and intestinal resection, early postoperative complications include anastomotic leak, adhesions formation, postoperative ileus, and wound infection. These are, however, rare (<5%). Intestinal obstruction from adhesions may present as a late event.

Bladder exstrophy: Considerations and management of the newborn patient

PETER P. STUHLDREHER AND JOHN P. GEARHART

INTRODUCTION

In this chapter, management of the newborn with classic bladder exstrophy (CBE) is discussed based on the authors' experience and data derived from more than 1250 patients with bladder exstrophy, epispadias, and cloacal exstrophy from an institutionally approved database at the authors' institution.

The primary objectives of modern surgical management of CBE are as follows: (1) a secure abdominal wall and pelvic closure; (2) reconstruction of a functional and cosmetically acceptable penis in the male, and female external genitalia in the female; and (3) urinary continence with the preservation of renal function and volitional voiding.

Currently, several techniques exist to reconstruct the newborn with bladder exstrophy. Regardless of the technique, successful primary closure with placement of the bladder and urethra deep in the pelvis is the most important step in achieving eventual continence with an appropriately sized bladder. In the authors' experience, these objectives can best be achieved with newborn primary bladder and posterior urethral closure, early epispadias repair, and finally, bladder neck reconstruction when the bladder reaches an appropriate volume for an outlet procedure and the child desires continence. This chapter will be limited to discussion on the early management and initial primary closure of these infants.

INCIDENCE AND INHERITANCE

The incidence of bladder exstrophy has been estimated to be roughly 1 in 50,000 live births.[1–3] The male-to-female ratio has been reported to be between 1:1 and as high as 6:1 live exstrophy births.[1,2,4] We typically quote a 3:1 male-to-female ratio for our patients and their families. The risk of recurrence of bladder exstrophy in a given family is approximately 1 in 100.[4] Shapiro et al.[5] determined that the risk of bladder exstrophy in the offspring of individuals with bladder exstrophy and epispadias is 1 in 70 live births, a 500-fold greater incidence than that in the general population.[5] In reviews of exstrophy patient cohorts, three interesting trends have been found: bladder exstrophy tended to occur in infants of younger mothers, with higher risk in the Caucasian race[2] and low or high socioeconomic status[2]; an increased risk at high parity was seen for bladder exstrophy and epispadias[4]; and an increased incidence occurs with in vitro pregnancies.[6]

EMBRYOLOGY

Bladder exstrophy, cloacal exstrophy, and epispadias are variants of the exstrophy–epispadias complex. The etiology of this complex has been attributed by Muecke[7] to the failure of the cloacal membrane to be reinforced by ingrowth of the mesoderm. The cloacal membrane is a bilaminar layer situated at the caudal end of the germinal disc, which occupies the infraumbilical abdominal wall. Mesenchymal ingrowth between the ectodermal and endodermal layers of the cloacal membrane results in formation of the lower abdominal muscles and pelvic bones. After mesenchymal ingrowth occurs, downward growth of the urorectal septum divides the cloaca into a bladder anteriorly and rectum posteriorly. The paired genital tubercles migrate medially and fuse in the midline cephalad to the dorsal membrane before perforation. This process begins during the third week of gestation and continues through the sixth week of gestation. If the cloacal membrane is subject to premature rupture, its stage of development when membrane rupture occurs determines if epispadias, bladder exstrophy, or cloacal exstrophy will result.[8] Based on the timing of this disruption, the severity of the defect is determined.[9–11]

While multiple explanations have been presented, experiments in chicken embryos support the Muecke hypothesis, with experimental destruction of the cloacal membrane leading to chicks born with exstrophy.[12] Classic exstrophy accounts for 60% of patients born with this complex.[13] Of these patients, 30% are epispadias variants, and 10% are cloacal exstrophies or minor variants, such as superior vesical fissure, duplicate exstrophy, and pseudoexstrophy.

Historically, the genetics of bladder exstrophy were unknown, but recent progress using genome-wide association studies have led to a possible target gene responsible for CBE. The *ISL1* gene encodes an insulin gene enhancer protein, a LIM zinc-binding/homeobox-domain transcription factor.[14] Murine models of this gene have shown its role in multiple developing tissues.[14] The pattern of inheritance of *ISL1* is neither recessive nor purely dominant.[14] Further work into clarifying and validating *ISL1* is ongoing.

ANATOMIC CONSIDERATIONS

Exstrophy of the bladder is part of a spectrum of anomalies involving the urinary tract, genital tract, musculoskeletal system, and sometimes the intestinal tract. In CBE, most anomalies are related to birth defects of the abdominal wall, bladder, genitalia, pelvic bones, rectum, and anus (Figure 80.1).

Figure 80.1 Newborn male infant with classic bladder exstrophy.

Musculoskeletal defects

Patients with CBE have a characteristic widening of the pubic symphysis caused by malrotation of the innominate bones, in relation to the sagittal plane of the body along both sacroiliac joints. In addition, they display an outward rotation or eversion of the pubic rami at their junction with the iliac bones. Using computed tomography (CT) of the pelvis with three-dimensional (3-D) reconstruction has further characterized the bony defect associated with both CBE and cloacal exstrophy.[15] Sponseller et al.[15] found that patients with CBE have a mean external rotation of the posterior aspect of the pelvis of 12° on each side, retroversion of the acetabulum, and a mean 18° of external rotation of the anterior pelvis, along with a 30% shortening of the pubic rami. The pelvic bones in children with CBE appear more like an open book or square shape compared to those of controls. These rotation deformities of the pelvic skeletal structures contribute to the short, pendular penis seen in bladder exstrophy. Additionally, this rotation also accounts for the increased distance between the hips, waddling gait, and the outward rotation of the lower limbs in these children, which in itself causes little disability and usually corrects to some degree over time.

A more recent study using 3-D CT has further increased our understanding of the pelvic anatomy in patients with bladder exstrophy.[16] The sacroiliac joints of bladder exstrophy patients are externally rotated, the pelvis is rotated inferiorly, and the pelvic volume is larger than in normal controls. One study, performed on fetal bony pelves with the exstrophy complex to determine histologic patterns and growth potential showed that despite the abnormal gross architecture, histologically, the exstrophic bone was identical to controls and completely normal; bone development was occurring at an expected rate with the potential for continued normal growth.[17]

In addition to the bony structures of the pelvis being laterally rotated, the large muscle groups constituting the pelvic floor are also flattened and laterally splayed. A fundamental tenet of bladder exstrophy repair is proper pelvic floor mobilization and placement of the vesicourethral complex deep within the pelvis. In 2001, Stec et al.[18] published the initial description using 3-D CT characterizing the pelvic floor in unclosed neonates with bladder exstrophy. This study found four primary findings that characterize the pelvic floor musculature in CBE: (1) the pelvic floor covers a twofold greater surface area in the exstrophy complex; (2) each levator ani half is outwardly rotated 38° from the midline; (3) the levator ani is 31° flatter in the exstrophy complex, thereby forming much less of a supportive sling than controls; and (4) only 32% of the puborectal sling is located anterior to the rectum for pelvic support as compared to 50% in controls. Magnetic resonance imaging (MRI) studies on the pelvic floor musculature created more advanced 3-D models of the abnormal character of the pelvic floor muscle, demonstrating one additional important caveat: the degree of pubic and bony diastasis does not account for all of the derangements in the pelvic floor anomaly

in exstrophy.[19] In addition, 3-D MRI has furthered our understanding of the soft tissue anomalies in exstrophy patients. There is significant alteration of the levator ani muscle group when compared to controls. The levators are located further anterior, are flattened, and offer limited support to the pelvic organs with associated anterior placement of the anus.[20] These data of 3-D MRI also have included postoperative imaging of exstrophy repair, providing 3-D imaging that shows that closure improves the overall appearance of pelvic musculature, so that it looks much more like that of controls.[20]

Abdominal wall defects

The triangular defect caused by the premature rupture of the abnormal cloacal membrane is occupied by the exstrophied bladder and posterior urethra. The fascial defect is limited inferiorly by the intrasymphyseal band, which represents the divergent urogenital diaphragm. This band connects the bladder neck and posterior urethra to the pubic ramus on anatomical study. The anterior sheath of the rectus muscles has a fanlike extension behind the urethra and bladder neck that inserts into the intrasymphyseal band. At the upper end of the triangular fascial defect is the umbilicus. In bladder exstrophy, the distance between the umbilicus and the anus is always foreshortened. Although an umbilical hernia is usually present, it is usually of insignificant size. The umbilical hernia is repaired at the time of the abdominal wall closure. Connolly et al., in a review of 181 children with bladder exstrophy, reported inguinal hernias in 81.8% of boys and 10.5% of girls.[21]

Anorectal defects

The perineum is short and broad, with the anus situated directly behind the urogenital diaphragm, displaced anteriorly, and corresponding to the posterior limit of the triangular fascial defect. The divergent levator ani and puborectalis muscles and the distorted anatomy of the external sphincter contribute to varying degrees of anal incontinence and rectal prolapse. Anal continence is usually imperfect at an early age but typically improves. Prolapse virtually always disappears after bladder closure. If the infant develops prolapse after closure, a bladder outlet obstruction must be ruled out.

Male genital defects

The male genital defect is severe and the most troublesome aspect of the surgical reconstruction, independent of the decision about whether to treat by modern staged closure, combined closure, or some form of urinary diversion. Formerly, it was thought that the individual corpus cavernosa were of normal caliber but appeared to be shorter because of the wide separation of the crural attachments, the prominent dorsal chordee, and the shortened urethral groove. However, data by Silver et al.[22] have described the genital defect in bladder exstrophy in much greater detail. Utilizing MRI in adult men with bladder exstrophy and comparing this to age- and race-matched controls, it was found that the anterior corporal length in male patients with bladder exstrophy is almost 50% shorter and 30% wider than that in normal controls. A functional and cosmetically pleasing penis can be achieved when the dorsal chordee is released, the urethral groove lengthened, and the penis somewhat lengthened by mobilizing the crura in the midline. Potency is preserved in almost all exstrophy patients. Testis function has not been studied in a large group of postpubertal exstrophy patients, but it is generally believed that fertility is not impaired by testicular dysfunction.

Female genital defects

Reconstruction of the female genitalia presents a less complex problem than in the male (Figure 80.2). The vagina is shorter than normal, hardly greater than 6 cm in depth, but of normal caliber. The vaginal orifice is frequently stenotic and displaced anteriorly; the clitoris is bifid. The labia, mons pubis, and clitoris are divergent. The uterus enters the vagina superiorly so that the cervix is in the anterior vaginal wall. The fallopian tubes and ovaries are normal. Female patients are typically able to bear children, but given the complexity of their reconstruction, cesarean section is mandated to protect pelvic structures. Even with precautionary cesarean section, adult females are at high risk of pelvic organ prolapse. Most adolescents and young adults will undergo a vaginoplasty procedure in order to wear tampons and have intercourse.

Urinary defects

At birth, the bladder mucosa may appear to be normal; however, ectopic bowel mucosa or an isolated bowel loop may be present. More commonly, a hamartomatous polyp may also be present on the bladder surface. The size, distensibility, and neuromuscular function of the exstrophied bladder, as well as the size of the triangular fascial defect to which the bladder muscles attach, affect the decision to attempt repair. When the bladder is small, fibrosed, inelastic, and covered with polyps, functional repair may be impossible. The bladder may be invaginated or may bulge through a small fascial defect, indicating the potential for satisfactory capacity after successful initial closure, which is commonly difficult to assess on initial

Figure 80.2 Female infant with classic bladder exstrophy.

exam. We strongly recommend examination under anesthesia to adequately diagnose true defect, as bladders that appear to be small in the nursery may have a substantial amount of bladder sequestered below the fascial defect.

The upper urinary tract is usually normal, but anomalous development does occur. Horseshoe kidney, pelvic kidney, hypoplastic kidney, solitary kidney, and dysplasia with megaureter are all encountered in these patients. The ureters have an abnormal course in their termination. The peritoneal pouch of Douglas between the bladder and the rectum is enlarged and unusually deep, forcing the ureter down laterally in its course across the true pelvis. The distal segment of ureter approaches the bladder from a point inferior and lateral to the orifice, and it enters the bladder with little or no obliquity. Due to this, the ureteral orifices are misplaced with an abnormal course of the submucosal ureters, leading, invariably, to vesicoureteral reflux,[23,24] which needs to be addressed at the time of the continence procedure.

PRENATAL DIAGNOSIS AND MANAGEMENT

It is possible to diagnose CBE prenatally with ultrasonographic findings.[25,26] The absence of a normal fluid-filled bladder on repeat examinations suggested the diagnosis, as did a mass of echogenic tissue on the lower abdominal wall.[26] In a retrospective review of 25 prenatal ultrasound examinations with the resulting birth of a newborn with CBE, several observations were made: (1) absence of bladder filling, (2) a low-set umbilicus, (3) widening of the pubic ramus, (4) diminutive genitalia, and (5) a lower abdominal mass, which increased in size as the pregnancy progressed and as the intra-abdominal viscera increased in size.[27] Surprisingly, despite very uniform ultrasound findings, even at high-volume centers, a majority of cases are diagnosed postnatally.[28] Prenatal diagnosis of bladder exstrophy allows for optimal management, including delivery in a pediatric center and appropriate prenatal counseling of the parents.

DELIVERY ROOM AND NURSERY CARE

At birth, while the bladder mucosa is usually smooth, pink, and intact, it is also sensitive and easily denuded. In the delivery room, the umbilical cord should be tied with 2-0 silk suture close to the abdominal wall so that the umbilical clamp does not traumatize the bladder mucosa and cause excoriation of the bladder surface. The bladder may be covered with a nonadherent film of plastic wrap (i.e., Saran Wrap) to prevent the mucosa from rubbing on clothes or diapers, leading to inflammation of the mucosa. In addition, each time the diaper is changed, the plastic wrap should be removed, the bladder surface irrigated with sterile saline, and a new square of plastic wrap placed.

The parents should be educated by a surgeon with a special interest and experience in managing cases of bladder exstrophy. An exstrophy support team should be available, which includes a pediatric orthopedic surgeon, pediatric anesthesiologists and postoperative pain team members, social workers, nurses with special interests in bladder exstrophy, and a child psychiatrist with experience and expertise in genital anomalies. It is important to note that the need for changing the sex of rearing in CBE is not advised.

Figure 80.3 Patient with a small fibrotic bladder patch deemed too small for neonatal closure. Note the polypoid nature of the bladder mucosa.

Cardiopulmonary and general physical assessment can be carried out in the first few hours of life. Ultrasound can provide evidence of renal structure, function, and drainage, even in the first few hours of life before the patient undergoes closure of the exstrophy defect, However, CBE is not heavily associated with significant renal defects. Radionucleotide imaging is reserved for a high index of suspicion for obstruction. A thorough neonatal assessment may have to be deferred until transfer of the child to a center of excellence.

Occasionally, a small fibrotic bladder template with an associated small triangular fascial defect without elasticity or contractility can be seen. When encountered, closure of these small bladders in a neonate should not be undertaken. Figure 80.3 shows a bladder that is too small for closure. Examination with the patient under anesthesia is required to assess the bladder adequately, particularly if considerable edema, excoriation, and polyp formation have developed between birth and the time of assessment. Decisions regarding the suitability of bladder closure or the need for waiting should only be made by surgeons with a great deal of experience in the bladder exstrophy condition. As illustrated by a review of our exstrophy database in 2001, it is infrequent that a bladder template is insufficient for closure.[29] After a period of time, when the bladder has grown sufficiently, closure was completed, and long-term follow-up revealed that 50% of these patients remained dry after bladder neck reconstruction and 50% required other adjunctive procedures.[29]

PRIMARY BLADDER CLOSURE

Over the past two decades, modifications in the management of functional bladder closure have contributed to a dramatic increase in the success of the treatment. The most

significant changes in the management of bladder exstrophy have been as follows: (1) early bladder, posterior urethra, and abdominal wall closure; (2) the widespread use of pelvic osteotomy along with appropriate pelvic immobilization; (3) epispadias repair at 6–10 months of age; (4) reconstruction of a competent bladder neck and reimplantation of the ureters; and (5) most importantly, defining strict criteria for the selection of patients suitable for this approach.

The primary objective of functional closure is to convert the patient with bladder exstrophy into one with complete male epispadias or reconstructed female epispadias with incontinence and balanced posterior outlet resistance that preserves renal function. Typically, epispadias repair is now performed between 6 and 10 months of age in the male, after testosterone stimulation. Bladder neck reconstruction occurs when the child is 4–5 years of age, has an adequate bladder capacity and is ready to participate in a preoperative and postoperative voiding program.

Another type of staged exstrophy repair is the Kelly repair, or radical soft tissue mobilization. In this repair, the bladder and abdominal wall are closed without osteotomy after birth. Several months later, a radical soft tissue mobilization and the urogenital diaphragm and its periosteal attachments are dissected and used to allow closure of the pelvis and pelvic floor. The penis is made hypospadiac, and later, penile repair is performed. Osteotomy is never used in this repair, and thus far, continence results are modest, with up to 71% of patients achieving either complete or partial continence in the largest cohort of patients reported in the literature.[30]

This chapter will deal with the most common issue seen by the pediatric surgeon, the primary closure. Obtaining a secure primary closure is the single most important step for achieving eventual continence in exstrophy patitents.[31] It cannot be stressed enough that proper patient selection and technique selection with liberal use of osteotomy are necessary for successful closure.

Pelvic osteotomy

Pelvic osteotomies performed at the time of closure offer several advantages, including the following: (1) easy reapproximation of the symphysis with diminished tension on the abdominal wall closure eliminating the need for fascial flaps, (2) placement of the urethra deep within the pelvic ring, enhancing bladder outlet resistance, and (3) bringing the large pelvic floor muscles near the midline, where they can support the bladder neck and aid in eventual urinary control.

After pubic approximation with osteotomy, some patients show the ability to stop and start the urinary stream, experience dry intervals, and in some cases, become completely continent.[32] In a review article of a large number of patients referred to the authors' institution with failed exstrophy, a majority were referred with partial or complete dehiscence of the bladder, or major bladder prolapse, and had not undergone osteotomy at the time of initial bladder closure.[33]

Our recommendation is to perform bilateral transverse innominate and vertical iliac osteotomy when bladder closure is performed after 72 hours of age.[34] In addition, if the pelvis is not malleable or if the pubic bones are >4 cm apart at the time of initial examination under anesthesia, osteotomy should be performed, even if closed before 72 hours of age. A well-coordinated surgical and anesthesia team can perform osteotomy and proceed to bladder closure without undue loss of blood or risk of prolonged anesthesia in the child. However, one must realize that osteotomy and posterior urethral and bladder closure, along with abdominal wall closure, is a 5- to 7-hour procedure in these infants.

Combined osteotomy is performed by placing the patient in the supine position, preparing and draping the lower body below the costal margins, and placing soft absorbent gauze over the exposed bladder. The pelvis is exposed from the iliac wings inferiorly to the pectineal tubercle and posteriorly to the sacroiliac joints. The periosteum and sciatic notch are carefully elevated, and a saw is used to create the transverse innominate osteotomy, exiting anteriorly at a point halfway between the anterosuperior and anteroinferior spines (Figure 80.4). This osteotomy is created at a slightly more cranial level than that described for a Salter osteotomy, in order to allow placement of fixator pins in the distal segments.

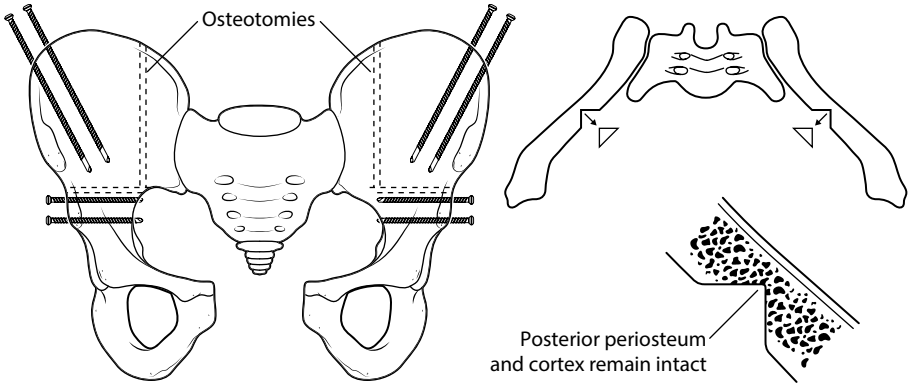

Figure 80.4 Combined transverse anterior innominate and anterior vertical iliac osteotomy with pin placement and preservation of the posterior periosteum and cortex.

In addition to the transverse osteotomy, the posterior iliac may be incised from the anterior approach in an effort to correct the deformity more completely. This is important because anatomical studies have shown that the posterior portion of the pelvis is also externally rotated in patients with exstrophy, and as patients age, they lose the elasticity of their sacroiliac ligaments. To achieve good closure, a closing wedge osteotomy is created vertically and just lateral to the sacroiliac joint. The proximal posterior iliac cortex is kept intact and used as a hinge. This combination of osteotomies easily corrects the abnormalities in both the anterior and posterior aspects of the pelvis.

Fixator pins are placed in the inferior osteotomized segment and in the wing of the ileum superiorly. The number of pins placed depends on the child's size and orthopedic surgeon discretion. Ideally, two pins are placed in either segment. Operative fluoroscopy is used to confirm pin placement. The soft tissues surrounding the osteotomy sites are closed, and the urologic procedure is then performed. At the end of the procedure, external fixators are then applied between the pins to hold the pelvis in a corrected position. Light longitudinal Buck's skin traction is used to keep the legs still. The patient remains in the supine position in traction for approximately 4 weeks to prevent dislodgement of tubes and destabilization of the pelvis. The external fixator is kept on for approximately 6 weeks until adequate callus is seen at the site of osteotomy. Postoperatively, in newborns who undergo closure without osteotomy in the first 48–72 hours of life, the baby is immobilized in modified Bryant's traction in a position in which the hips have 90° flexion. When modified Bryant's traction is used, it is employed for 4 weeks. During this time, movement control is critically important, and use of tunneled epidural catheters for pain control and use of anesthesia pain colleagues for movement control and postoperative sedation are advised.

Bladder, posterior urethral, and abdominal wall closure

The various steps in primary bladder closure are illustrated in Figure 80.5. A strip of mucosa 2 cm wide, extending from the distal trigone to below the verumontanum in the male and to the vaginal orifice in the female, is outlined for prostatic and posterior urethral reconstruction in the male and adequate urethral closure in the female. The male urethral groove length is typically adequate, and no transverse incision of the urethral plate needs to be performed for urethral lengthening. The diagrams in Figure 80.5a–c show marking of the incision with a marking pen from just above the umbilicus down around the junction of bladder and the paraexstrophy skin to the level of the urethral plate. The approximate plane is entered just above the umbilicus, and a plane is established between the rectus fascia and the bladder (Figure 80.5c,d). The umbilical vessels are doubly ligated and incised, allowing them to fall into the pelvis. The peritoneum is taken off the dome of the bladder at this point so that the bladder can be placed deeply into the pelvis at the time of closure. Radical dissection of the peritoneal reflection from the bladder should not be done, as the vasculature to the exstrophied bladder often will occupy this space and can be inadvertently compromised. The plane is continued caudally between the bladder and the rectus fascia until the urogenital diaphragm fibers are encountered bilaterally. The pubis will be encountered at this juncture, and use of a double-pronged skin hook into the bone will accentuate the urogenital diaphragm fibers and help the surgeon radically incise these fibers between the bladder neck, posterior urethra, and pubic bone. Gentle traction on the glans of the penis at this point will show the insertion of the corporal body in the lateral inferior aspect of the pubis. These urogenital fibers are taken down sharply with electrocautery to the pelvic floor in their entirety. If this maneuver is not performed adequately, the posterior urethra and bladder will not be placed deeply into the pelvis and will compromise closure. As well, when the pubic bones are brought together, the posterior vesicourethral unit will be brought anteriorly in an unsatisfactory position for later reconstruction.

The corporal bodies are not brought together at this juncture, as later Cantwell–Ransley epispadias repair will require the urethral plate to be brought beneath the corporal bodies. If the urethral plate is left in continuity, it must be mobilized up to the level of the prostate in order to create as much additional urethral and penile length as possible. Further urethral lengthening can be performed at the time of epispadias repair, around 6 months of age.

Apparent penile lengthening is achieved by exposing the corpora cavernosa bilaterally and freeing the corpora from their attachments to the suspensory ligaments on the anterior part of the inferior pubic rami. It is important to note that there is a 50% shortage of length in the corporal bodies in exstrophy patients versus normal controls, and any penile lengthening that is obtained is more correction of chordee and changing the angulation of the penis rather than true penile lengthening.[22]

After their incision, the wide band of fibers and muscular tissue representing the urogenital diaphragm is detached subperiosteally from the pubis bilaterally (Figure 80.5e,f). Reluctance to free the bladder neck and urethral wall from the inferior ramus of the pubis moves the neobladder opening cephalad if any separation of the pubis occurs during healing. The mucosa and muscle of the bladder and the posterior urethral wall into the penis are then closed in the midline anteriorly. This orifice should accommodate a 12- to 14-French urethral catheter comfortably. The size of the opening should allow enough resistance to aid in the bladder adaptation and to prevent prolapse but not enough outlet resistance to cause upper tract changes. The posterior urethra and bladder neck are buttressed to the second layer of local tissue if possible (Figure 80.5g,h). The bladder is drained by a suprapubic nonlatex Malecot catheter for a period of 4 weeks. The urethra is not stented, in order to avoid necrosis with accumulation of secretions in the neourethra. Postoperatively, careful attention should be paid

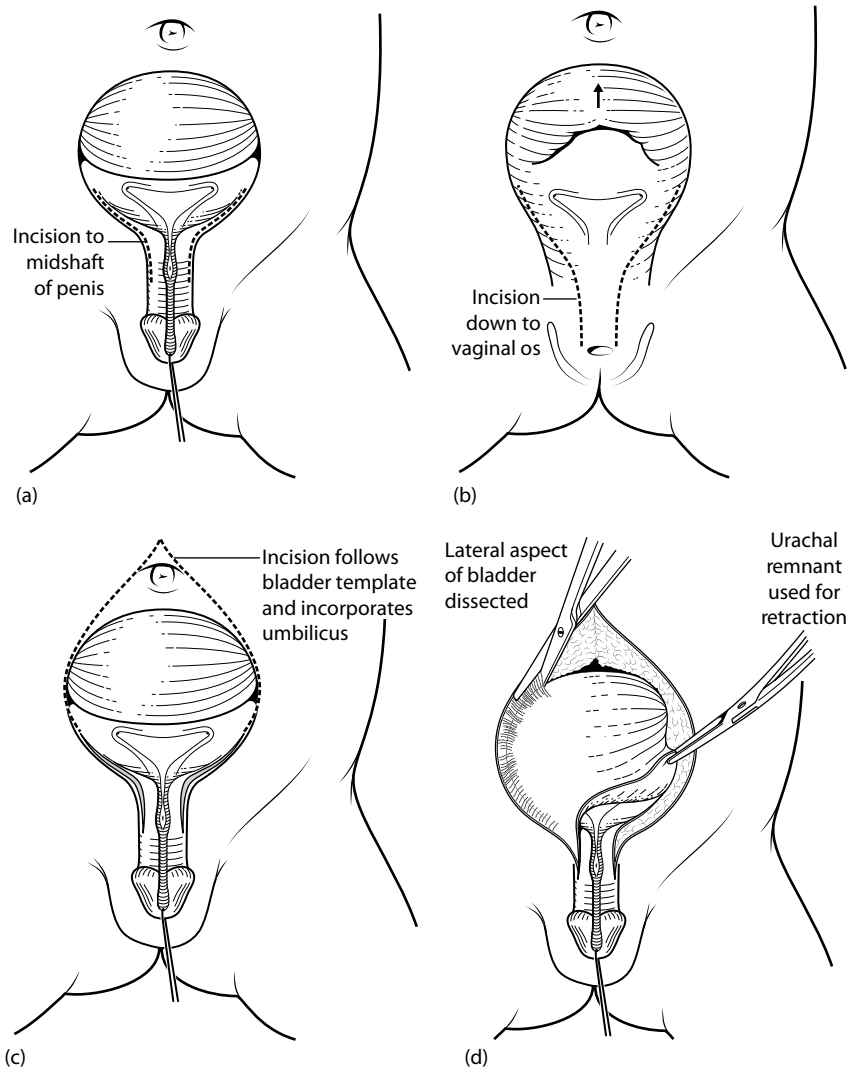

Figure 80.5 **(a)** Marking of the initial incisions for a male exstrophy patient from trigone around urethral plate. **(b)** Marking of comparable incisions for closure of a female exstrophy patient down to vaginal os. **(c)** Marking of the subsequent incision around the umbilicus and bladder, joining the initial dissection. **(d)** Development of the retropubic space and division of the lateral bladder attachments. to pooling of urine in the epispadias, as continued urine soilage can compromise repair or lead to soft tissue infection due to the immobilization of the child. Ureteral stents provide drainage for 10–14 days after closure, when swelling due to the presence of closure of a small bladder may obstruct the ureters and give rise to obstruction and transient hypertension. These stents are left in place, however, for the duration of pelvic external fixation, if used, and the duration of traction.

When the bladder and urethra have been closed and the drainage tube placed, pressure over the greater trochanters bilaterally allows the pubic bones to be approximated in the midline. Horizontal mattress sutures of number 2 nylon are placed in the pubis and tied with a knot away from the neourethra (Figure 80.5h). Oftentimes, in a good closure, the authors are able to use another stitch of number 2 nylon at the most caudal insertion of the rectus fascia into the pubic bone. This maneuver will add to the security of the pubic closure. Research has shown that the choice of suture for pelvic closure is critically important, with nylon showing superior tensile strength compared to other choices.[35] A V-shaped flap of abdominal skin at a point corresponding to the normal position of the umbilicus is tacked down to the abdominal fascia, and the drainage tubes exit this orifice. The method described by Hanna[36] is the authors' most commonly performed procedure. Before and during the procedure, the patient is given broad-spectrum antibiotics in an attempt to convert a contaminated field into a clean surgical wound. Nonreactive sutures of polyglycolic acid (Dexon/Vicryl) and nylon are used to avoid an undesirable stitch reaction or stitch abscess.

Combined bladder closure and epispadias repair

The modern staged closure of bladder exstrophy has yielded consistently good cosmetic and functional results, and the utilization of osteotomy has improved the potential for successful initial closure and later continence. In an effort to decrease costs and the morbidity associated with multiple operative procedures, and possibly to effect continence, there is current interest in performing single-stage reconstruction, or combining procedures in appropriately selected patients. This technique was first described by Lattimer and Smith[1] for primary closures and Gearhart and Jeffs[37] in 1991 for failed exstrophy closures. Grady and Mitchell[38] have renewed interest in its use in newborn patients, and results have now been reported in groups of boys undergoing single-stage reconstruction (bladder closure and epispadias repair) in infancy.

The complete primary repair of bladder exstrophy is now being performed in neonates at several centers worldwide. The basics steps of the procedure have been outlined by Grady and Mitchell.[38] The initial dissection begins superiorly and is carried inferiorly to isolate the bladder template. This is carried down in a continuous fashion to then begin the penile dissection ventrally. The penile dissection will progress medially with care being taken to preserve

the urethral plate for later tubularization. As previously described by Mitchell, the penis will be completely disassembled into individual corporal bodies and urethral plate with supporting spongiosum tissue.[39] Deep proximal dissection is undertaken to free the veriscourethral unit from the intersymphyseal ligaments to provide deep placement of the unit into the pelvis. Once the dissection is complete, the bladder is closed, the penis is reassembled anatomically with a hypospadiac urethra, and the abdominal wall and skin closure is completed.[38]

Long-term results of 39 children have been published that show that in experienced hands, this procedure produces comparable success rates.[40] Of children aged 4 years or older who underwent complete primary repair, 74% are continent in daytime with volitional voiding. Importantly, only 20% of boys and 43% of girls achieved primary urinary continence without the need for bladder neck reconstruction. Complication rates were comparable at 18%, with five urethrocutaneous fistulas and two patients with fascial dehiscence. However, there are published reports of significant complications from the complete primary repair. There have been multiple reports of significant penile tissue loss from complete primary repair and associated closure failures.[41–43] In a review of patients referred to our institution after complete primary repair, 13 of 55 males had major penile soft tissue loss.[44]

In the current authors' opinion, this technique should be limited to boys of older age (older than 6 months of age) because of recent experimental evidence indicating that newborn exstrophy bladders differ from bladders in older infants in the level of maturity of the muscle and connective tissue components. The senior author believes that these patients should be carefully selected, especially newborns, because of the reasons given earlier. Otherwise, boys presenting after failed initial closure and/or older than 6 months of age may be candidates for a combination of epispadias repair with bladder closure. Children should be carefully selected based on phallic size, length and depth of the urethral groove, size of the bladder template, and perivesical and urethral plate scarring in those who have undergone a prior failed closure.

CONCLUSION

The modern staged approach to treatment in patients with bladder exstrophy is able to provide a satisfactory outcome both cosmetically and functionally in most cases. This approach consists of the following: (1) initial bladder closure, (2) repair of epispadias, and (3) bladder neck reconstruction. Bladder neck reconstruction is the recommended management based on the current authors' and institutional experience with over 941 cases of the exstrophy–epispadias complex. Recent reports of a single-stage repair by other authors have proposed successful outcomes; however, follow-up is limited, and numbers of patients in these series is small. In the modern staged repair, the continence rate for males with exstrophy voiding per urethra is 80.6%, with 70% dry around the clock and 10.6% dry during the day but damp at night.[45] In females, 74% were voiding per urethra and continent 24 hours a day, with an additional 10% being continent during the day while wet at night.[46] While recent developments in tissue engineering hold promise to improve outcomes for patients requiring genitourinary reconstruction in the future, staged functional closure remains the gold standard for patients with CBE.

Cloacal exstrophy

ALONSO CARRASCO JR., DUNCAN T. WILCOX, AND VIJAYA M. VEMULAKONDA

INTRODUCTION

Cloacal exstrophy is an extremely rare congenital disorder first described by Littre in 1709.[1] It is the most severe form of the bladder exstrophy–epispadias complex and is characterized by findings of two exstrophy hemibladders, exstrophy hindgut, underdevelopment of hindgut, pubic diastasis, prolapsing terminal ileum, complete separation of genitalia, and omphalocele (Figure 81.1). The first successful treatment of cloacal exstrophy using a three-stage procedure was described by Rickman in 1960.[2] Since then, advances in medical and surgical care have improved survival to over 80%.[3,4] With this drastic increase in survival, the goals of care have shifted toward improvement of early diagnosis, preservation of the function of affected organs, and improvement in quality of life.

EMBRYOLOGY

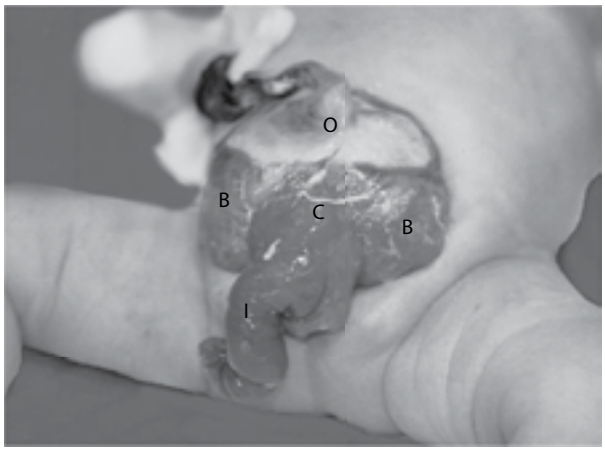
The exact embryology and etiology of cloacal exstrophy are still poorly understood, but several theories have been postulated. The most commonly supported theory is the failure of mesodermal tissue migration to the lateral fold, leading to premature rupture of the cloacal membrane before the urogenital septum divides the cloaca into the anterior urogenital sinus and posterior anorectal canal.[5,6] This results in a large midline defect with exposure of both bladder and bowel elements and complete separation of the genitalia. This theory is supported by induction of cloacal exstrophy in animal models by inducing premature rupture of the cloacal membrane.[6,7] However, cases of cloacal exstrophy with intact or delayed rupture of the cloacal membrane and covered variants raise questions about this explanation.[8–11] Additionally, histopathological studies in human embryos support a much earlier defect involving the caudal eminence of the trilaminar embryo.[12,13] Other theories include insufficient cell deposition or malfunctioning of the umbilical ectodermal placode leading to impaired body wall formation.[14,15]

EPIDEMIOLOGY, GENETICS, AND ENVIRONMENTAL RISK FACTORS

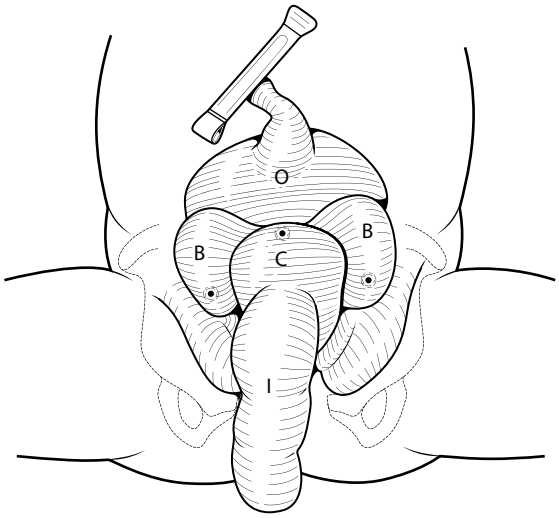
Cloacal exstrophy has an overall prevalence of 1 in 200,000–300,000 live births.[16,17] Historically, there has been a male-to-female predominance of 2:1, but in recent epidemiological studies and large series, the male-to-female ratio is more evenly distributed.[16,18,19] It is often sporadic, with no genetic defect or environmental factor definitively identified as the cause of cloacal exstrophy. Small familial recurrence rate and concordance in monozygotic twins support a genetic basis in some cases.[18,20] Methylenetetrahydrofolate reductase polymorphism C677T was recently found to have a strong association with cloacal exstrophy.[21] Other gene and chromosomal abnormalities implicated include the HOX gene family, trisomy 13, trisomy 18, 9q34.1-qter deletion, del(3)(q12.2q13.2), 1p36 deletion, and mitochondrial 12SrRNA deletion.[22–27] Studies evaluating environmental factors are scarce and focused on small geographical areas or populations. Use of clomiphene citrate around time of conception was previously implicated,[28] but a prospective study later refuted this association.[29] Small case series have also suggested in vitro fertilization and smoking as potential risk factors.[18,30]

PRENATAL DIAGNOSIS

With the advent of prenatal imaging, more patients are now being diagnosed prenatally either by ultrasound or with the aid of fetal magnetic resonance imaging (MRI). Several criteria have been proposed for diagnosis. Major criteria include nonvisualization of the bladder, a large midline infraumbilical anterior wall defect or cystic anterior wall structure, omphalocele, and/or lumbosacral anomalies.[31] Other proposed minor criteria include lower extremity defects, renal anomalies, ascites, widened pubic arches, narrowed thorax, hydrocephalus, and solitary umbilical artery.[31] Additionally, the prolapsing of the terminal ileum resulting in an "elephant trunk–like"



(a)



(b)

Figure 81.1 **(a)** A patient with cloacal exstrophy and **(b)** a diagram depicting the component parts of the deformity. A prolapsing terminal ileum (I) depicting the elephant trunk deformity is demonstrated with cecal place (C) between the two hemibladders (B) and omphalocele superiorly (O).

image on prenatal ultrasound has been deemed a pathognomonic finding.[32] Despite these predictive criteria, prenatal ultrasound remains a poor predictor of diagnosis, with only 25% of patients with bladder/cloacal exstrophy diagnosed by prenatal ultrasound.[33] Fetal MRI is an adjunct image modality that has been more recently used to aid in the prenatal diagnosis. Case series of this have demonstrated excellent diagnostic accuracy and the added benefit of better characterization of associated anomalies.[34–36]

Early diagnosis of cloacal exstrophy allows for early family counseling regarding extent of congenital defect, associated abnormalities, required surgical reconstruction, and long-term outcomes. Equally important, prenatal diagnosis helps with making arrangements for delivery of a patient at a center with capabilities and expertise in the postnatal management of this complex condition. It also allows for the parents to evaluate the alternative of elective termination of pregnancy, which has been reported in up to 33% of cases.[33,37]

ASSOCIATED ANOMALIES

Cloacal exstrophy often presents as part of one of three complexes: omphalocele–exstrophy–imperforate anus (OEI), omphalocele–exstrophy–imperforate anus–spinal defect (OEIS), or the exstrophy–imperforated anus–spinal defect (EIS) complex. As a result, patients should be evaluated for associated neurologic, skeletal, genitourinary, and gastrointestinal (GI) anomalies. Neurologic anomalies arise from concomitant spinal dysraphism (including tethered cord) in 64%–100% of cases.[37–41] This results in significant long-term neurologic morbidity as bladder, GI, lower extremities, and erectile function can be impaired. In addition to the bladder being affected by spinal dysraphism, there are data to support aberrant neurovascular supply to the bladder at risk for iatrogenic injury at the time of reconstruction.[42] Approximately 31% of patients with spinal dysraphism also have intracranial abnormalities such as hydrocephalus and Chiari malformation.[43] Other skeletal anomalies such as extra vertebrae, hemivertebrae, scoliosis, and kyphosis have been reported in 22%–60% of patients.[42,44] Limb deformities are also observed in 17%–26% of patients.[45]

Associated genitourinary anomalies are common. Abnormalities of the upper urinary tract have been reported in 41%–66% of patients[3,19,46,47] with renal anomalies including pelvic kidney, hydronephrosis, and renal agenesis, seen in one-third of patients.[47] In females, external and internal genitalia are affected in 73%–97% of cases.[48–50] Various degrees of duplication of Müllerian structures along with vaginal agenesis, atresia, or transverse septa are common. Ovaries are generally histologically normal.[51] The labia and clitoris are widely separated, and absence of clitoral halves may be seen. In males, the scrotum and phallic structure are similarly widely separated, and the phallic halves may be diminutive or absent (aphallia). The phallic structure can occasionally be found intravesically.[52] Cryptorchidism is common, but the testes are histologically normal.[53]

The most common GI anomalies include omphalocele, exstrophy of the cecal plate, blind-ending hindgut, and imperforate anus. Additional anomalies include short bowel syndrome, colonic duplication, duodenal web, Meckel diverticulum, malrotation, and duodenal atresia.[54] GI anomalies are associated with significant morbidity due to increase risk of nutritional malabsorption or obstruction.[38]

IMMEDIATE POSTNATAL MANAGEMENT

Cloacal exstrophy should be managed by a multidisciplinary team comprising a pediatric urologist, pediatric surgeon, neonatologist, pediatric neurosurgeon, pediatric endocrinologist, and pediatric orthopedic surgeon at a center with interest and experience in the management of this complex condition. A psychiatrist/psychologist and social

worker well versed in gender assignment issues should be involved early in the process to aid with family care.[55] Upon delivery and stabilization of the neonate, all mucosal surfaces such as the exposed bladder plates, omphalocele, intestines, and myelomeningoceles should be protected. A cling-film dressing (Saran Wrap) moistened with saline can be used to cover the exposed mucosa, or a bowel bag can be use to enclose the infant's lower torso. This helps to minimize fluid losses, mucosal damage, and infection. The umbilical cord should be ligated with a nonabsorbable suture to prevent abrading the bladder plate or the hindgut with the standard umbilical clamp. Routine preoperative labs (electrolytes, hematologic, and renal function) should be drawn along with karyotyping. Preoperative imaging including renal ultrasound, chest x-ray, and spinal imaging with ultrasound or MRI should be obtained to evaluate for associated anomalies. Intravenous access should be obtained in the upper limbs to allow surgical access to the lower half of the neonate. If not done prenatally, preoperative counseling should include surgical reconstruction, gender assignment in males, anticipated needs for future surgery, and potential complications or deficits that may result in the long term.

GENDER ASSIGNMENT

Females (46XX) with cloaca exstrophy should be raised as females. Gender assignment in male (46XY) patients with cloacal exstrophy remains a complex and controversial issue. Historically, patients with insufficient phallic tissue or aphallia were reassigned and raised as female. This was accomplished by performing early orchiectomy and subsequent feminizing reconstruction. However, this practice has recently been brought into question. In a survey of pediatric urologists, two-thirds favored male gender assignment primarily based on concerns of prenatal testosterone imprinting.[53,56] In addition, studies have also demonstrated that over half of male cloacal exstrophy patients reassigned as female question their gender, exhibit stereotypical male behavior, have sexual interest in females, or declare themselves as male.[23,39,57,58] While current views are to maintain male gender, it is important that this decision be made as part of a multidisciplinary team with significant input from the family.

POSTNATAL SURGICAL MANAGEMENT

Initial surgical management should be undertaken in the newborn period (48–72 hours). Early operation minimizes bacterial colonization of exposed organs and may reduce the need for osteotomies.[39,59,60] An individualized approach to each patient usually dictates the extent of the initial surgery. The order of the repair is usually closure of the omphalocele first, followed by separation of the hemibladders from the exstrophic hindgut, tubularization of hindgut with salvage of all bowel segments including the appendix, creation of an end bowel ostomy, approximation of the hemibladders in the midline, and if feasible, closure of bladder and abdominal wall defect. If a spinal dysraphism is present, it may also be addressed at the time of initial surgery. The genitalia are managed either during initial repair or as part of a subsequent procedure. Table 81.1 outlines a typical management plan for cloacal exstrophy.

When omphalocele closure is not possible, a silo device may be required in order to minimize abdominal compartment syndrome and decrease the risk of wound dehiscence.

Table 81.1 Outline of typical management plan for cloacal exstrophy

Management phase	Patient age	Therapeutic procedures
Phase 1	Newborn	Meningocele coverage (when present) Closure/coverage of omphalocele Separation of bowel/bladder plates Bowel reconstruction/tubularization Hemibladder approximation ± closure Gender assignment (early orchiectomy) Genital reconstruction (complete or first stage) Pubic bone approximation (±osteotomies)
Phase 2	1–6 months	Feeding access Management of short bowel syndrome
Phase 3	6 months–2 years	Bladder closure if not done Pubic bone approximation with osteotomies Genital reconstruction (complete or first stage)
Phase 4	2–18 years	Genital reconstruction (second stage or for gender reassignment) Bladder neck reconstruction or other continence procedure (sling, artificial urinary sphincter, etc.) Bladder augmentation Construction of catheterizable channel

A 5-French ureteral catheter should be inserted into each ureter and secured to the bladder mucosa to aid in ureteral identification during dissection and prevent postoperative obstruction. Dissection should start superiorly with ligation and division of umbilical vessels. The two hemibladders are then separated from the hindgut using diathermy, taking care to avoid the ureters. Meticulous dissection medial to the hemibladder must be performed in order to avoid iatrogenic injury of the bladder or the nerves of the corporal bodies, which travel in the midline along the posteroinferior surface of the pelvis before extending laterally.[42] If the patient has an absent hemiphallus or is aphallic, one should evaluate for potential intravesical phallic structures.[52] Preservation of all bowel segments including the appendix cannot be overemphasized due to the risk of short bowel syndrome and potential need for future urinary tract reconstruction.[39,61] It is recommended that the tubularized hindgut be turned into an end colostomy or left as a mucus fistula.[55] If possible, an ileostomy should be avoided as this can lead to fluid, electrolyte, and nutritional issues.[62,63] Bowel length should be measured and documented. The hemibladders should be approximated in the midline, thus converting the condition into a classic bladder exstrophy for subsequent staged repair.

At this point, it is usually determined if a single-stage or multistage repair is appropriate based on patient medical status, other congenital anomalies, and anatomic findings that may preclude primary single-stage repair. Studies have suggested comparable outcomes with single-stage and multistage repairs.[64,65] If the bladder plate is of adequate size and a single-stage repair is feasible, the bladder plate is dissected from its lateral attachment and lateral edges are approximated in the midline using absorbable suture. The bladder neck and proximal urethra are tubularized over an 8-French catheter either completely in girls or partially in boys (thus creating an epispadias). Ureteral stents can be brought out via the neourethra or via the anterior abdominal wall during bladder closure. The next step is genital reconstruction, which can be extremely challenging in males with cloacal exstrophy. Phallic halves are usually widely separated, asymmetric, absent, and/or rudimentary. Phallic reconstruction and epispadias repair is usually accomplished at a later time. Reconstruction during initial closure can be performed following the same principles as in classic bladder exstrophy. Current practice is to reapproximate the hemiscrota in the midline and, if necessary, perform orchiopexy. Genital reconstruction in females is usually done at the time of bladder closure. The medial aspect of the hemiclitoris may be denuded of mucosa, and the halves are brought together in the midline along with the labia minora. Müllerian structures are usually duplicated and should be joined in the midline and brought to the perineum during initial repair.

Similar to classic bladder exstrophy, placement of the bladder and proximal urethra deep in the pelvis is a key factor for success. To accomplish this, the pubic symphysis is approximated in the midline with interrupted high-tensile-strength suture. Pelvic osteotomies can be employed to improve success with closure by decreasing tension on the wound.[19,66,67] If the surgery is performed early in the neonatal period, there appears to be no difference in terms of wound dehiscence between patients with and without osteotomies.[60] The abdominal wall muscle and skin are then closed in layers with absorbable sutures.

POSTOPERATIVE MANAGEMENT

Close postoperative monitoring in the neonatal intensive care unit is necessary to ensure adequate pain control, immobilization, and nutritional support. Patients should remain immobilized for 4–6 weeks using one of a variety of described traction devices.[68–70] Avoiding abdominal distention is also important to prevent tension on the wound. Initial and aggressive use of total parental nutrition is advocated given the risk of short bowel syndrome.[71] Prophylactic antibiotics to cover for skin flora and urinary pathogens is recommended given the presence of multiple long-term indwelling catheters and associated 50%–60% risk of associated vesicoureteral reflux.[46] Serial ultrasound imaging of the kidneys is recommended to ensure adequate urinary drainage. Laboratory tests may be obtained as needed to evaluate for electrolyte disturbances and adjust nutrition supplementation.

UROLOGIC MANAGEMENT

Timing of ureteral and urethral catheter removal depends on surgeon preference and patient status. Sequential removal of stents along with upper tract monitoring with renal ultrasound is necessary to ensure adequate drainage. Once all catheters are removed, the patient should be monitored for spontaneous voiding and assessed for high postvoid residuals that may require initiation of intermittent catheterization. Bladder outcomes appear to be less favorable than those of classic bladder exstrophy, and achieving continence remains a challenge. Over 40% of patients have persistent incontinence after primary repair.[19,40,72,73] This high rate of incontinence is attributed to a smaller bladder plate and higher risk of associated neurologic condition.[40] Multiple approaches for urinary tract reconstruction to achieve continence have been described, including bladder neck reconstruction, slings, artificial urinary sphincter implantation, and bladder neck closure.[74–76] Patients often undergo multiple procedures, but a catheterizable channel and augmentation cystoplasty are necessary to achieve continence in over 50% of patients.[19,39,75,77] Patients with cloacal exstrophy should be followed closely by a pediatric urologist given the risk of bladder and upper tract deterioration associated with spinal dysraphism.

GI OUTCOMES

A considerable proportion of patients have morbidity related to the GI tract. Preservation of as much bowel

as possible during initial repair is paramount as it will optimize bowel absorption by increasing transit time. It is also reported that there is potential for colonic growth with time, and any bowel segment can be of benefit during future reconstructions of the urinary tract.[39,61,78] Patients with cloacal exstrophy have traditionally been managed with diverting ostomy due to associated spinal dysmorphism, abnormal pelvic and sacral anatomy, and the absence of normal sphincter mechanisms.[78] However, several series have demonstrated good outcomes with pull-through procedures in select patients, with fecal continence in over 76% of patients using adjunct bowel management including a bulking diet, antidiarrheal medications, and enemas (antegrade or retrograde).[39,78] The ability to form solid stool and colonic length are key factors to achieving fecal continence rather than the presence of intact sphincter mechanisms.[61,63]

SEXUAL FUNCTION AND QUALITY OF LIFE

There are limited data on male patients with cloacal exstrophy with regard to sexual function and quality of life. A report of eight male patients with cloacal exstrophy demonstrated phallic inadequacy in all and erectile dysfunction in half, and only one was able to engage in vaginal intercourse.[60] While there are no reports of males with cloacal exstrophy fathering children, assisted reproductive technology can certainly be an option for these patients given normal testes.[53] Recent advancements and future developments in the field of phallic reconstruction and penile transplantation hold promise for male patients with cloacal exstrophy.[79–82] Total phallic construction using the radial artery–based forearm free flap has demonstrated excellent patient satisfaction with regard to phallic cosmesis, size, and ability to achieve sexual intercourse with the aid of a penile prosthesis.[81]

Vaginal reconstruction in female patients with cloacal exstrophy is also challenging. This is generally performed during initial repair if feasible, but oftentimes, delayed repair and additional procedures are necessary. Over 65% of patients have duplication of the vagina, uterus, or fallopian tubes due to failed fusion of the Müllerian ducts.[50,83] Pull-through vaginoplasty, flap/graft vaginoplasty, creation of neovagina using bowel, and use of the native bladder to create a neovagina have been reported.[39,61,83] There are few reports on the outcome of the uteri, but approximately half of patients require total or partial hemihysterectomy due to hydrometrocolpos, prolapse, or underdevelopment.[50] Reports on sexual function, while limited and small, demonstrate that up to half of female patients are sexually active and the majority are satisfied with their sexual life.[84,85] Successful pregnancy, although complicated and high risk, has been reported.[84,86,87] Long-term quality-of-life studies are limited in this patient population, although cases series suggest that the majority of patients are satisfied with their professional and social life.[84]

CONCLUSIONS

With advances in perinatal management and surgical reconstruction, mortality in patients with cloacal exstrophy has significantly decreased, and emphasis in care has shifted to improved diagnosis, surgical outcomes, and quality of life. Gender identity, continence, and body image can impact the quality of life of these patients, and efforts to improve in these areas are needed. Because of the rarity of this congenital condition and the lack of data, the optimal management strategy remains unclear. Treatment should be individualized to the needs of the patient and family at a center with the multidisciplinary expertise needed to adequately care for patients with this rare condition.

Prune belly syndrome

SALVATORE CASCIO, HIDESHI MIYAKITA, AND PREM PURI

INTRODUCTION

Prune belly syndrome is characterized by a triad of abnormalities, including an absence or deficiency of abdominal wall musculature, cryptorchism, and anomalies of the urinary tract. The characteristic deficiency of the abdominal wall musculature was first described by Frohlich et al.[1] in 1839. Parker[2] first reported the association of the genitourinary anomalies with the deficient abdominal musculature. The term "prune belly syndrome" was coined for this complex by Osler in 1901.[3] Eagle and Barrett,[4] in 1950, further defined the triad of absent abdominal wall musculature, undescended testes, and urinary tract abnormalities. The incidence of prune belly syndrome is estimated to be 1 in 27,000 to one in 40,000 live births.[5–7] This syndrome occurs almost exclusively in boys. In females, it is extremely rare, with less than 50 cases described in the world literature.[7,8] It is also known as *pseudo–prune belly syndrome* and is characterized by hypoplastic abdominal musculature and urinary tract and genital anomalies, most commonly bicornuate uterus and vaginal atresia.[8]

ETIOLOGY

The pathogenesis of prune belly syndrome remains controversial, and many theories have been proposed to explain it.[3,4] One theory proposes that prenatal obstruction or dysfunction of the urinary tract causes urinary tract dilatation, fetal abdominal distension, and subsequent muscle wall hypoplasia and cryptorchism in males.[9–12] An embryological theory proposes that failure of primary mesodermal differentiation leads to defective muscularization of both the abdominal wall and the urinary tract.[10–12] Although both theories explain some elements of the syndrome, they fail to explain others. Reinberg et al.[8] recently suggested that the two theories should be regarded as complementary mechanisms, both operating in any given case. They theorized that teratogenic agents produce abnormal development of derivatives of the lateral plate mesoderm and abnormal epithelial–mesenchymal interactions, resulting in abnormal organ development and mechanical or functional obstruction of the urinary tract. Stephens and Gupta[13] proposed a theory of abnormal development of the intermediate mesoderm as a key factor in the pathogenesis of prune belly syndrome. This theory has two features: the first is that the terminal part of the Wolffian duct is incorporated into both the prostatic and membranous urethra, and the second is that during incorporation, the ducts including their ureteric buds overexpand. Abnormal ectasia of the terminal Wolffian duct occurring between 6 and 10 weeks' gestation may produce saccular dilatation of the prostatic urethra, prostatic hypoplasia, and the valve-like obstruction in the membranous urethra. The ectasia could explain the attenuated bladder trigone and laterally placed wide ureteric orifices. Involvement of ureteric buds may also produce irregular megaureters. Renal dysplasia can be explained as a result of primary dysplasia of the metanephros or secondary to ureteric ectopia.

The genetic basis of prune belly syndrome remains unknown. A single-gene abnormality or chromosomal defect has been suggested as the cause of this syndrome. There is an especially high incidence of prune belly syndrome associated with trisomy 21,[14] trisomy 13,[15,16] and trisomy 18.[17,18] Twelve published case reports of familial prune belly syndrome primarily affecting brothers have suggested a possible autosomal or X-linked recessive mode of inheritance.[19,20] *HNF1*β is a transcription factor that regulates gene expression for normal mesodermal and endodermal development and has been proposed as a possible candidate gene for the syndrome. The most common *HNF1*β phenotype is renal cysts and diabetes syndrome, also called maturity-onset diabetes of the young type 5.[21] However, a recent study has detected the V61G *HNF1*β mutation only in 1 of 34 (3%) patients with prune belly syndrome.[20]

PATHOLOGY

Abdominal wall

Prune belly syndrome represents a spectrum of disease severity, ranging from those that die within the first few days of

Figure 82.1 A newborn with typical features of prune belly syndrome. Note the shriveled prune-like appearance of the abdominal wall and patent urachus.

life to those that survive with relatively stable renal function in childhood. The most obvious defect in newborns with the syndrome is the shriveled prune belly–like appearance of the abdominal wall due to a deficiency in the abdominal wall musculature (Figure 82.1). The affected muscles in decreasing order of frequency are the transversus abdominis, rectus abdominis below the umbilicus, and internal oblique, external oblique, and rectus abdominis above the umbilicus.[22–24] Biopsy from the abdominal musculature shows that major functioning or recoverable muscle exists in the lateral and upper sector of the abdomen, but that little or no muscle exists in the lower central abdomen.[25] Light microscopy shows a thin mass of muscle tissue with an irregular pattern of fatty infiltration interdigitated with the muscle. Electron microscopy shows a loss of coherence and internal orientation.[26] Z-bands are shattered and disarranged, and glycogen granules are clumped in various areas. The abdominal wall defect may result in chronic constipation and respiratory infection. In addition, this defect increases the risk of postoperative pulmonary complications in patients who undergo general anesthesia. It is also impossible for the patient with a complete manifestation of the triad syndrome to raise himself/herself from the supine position to the sitting position without using the arms or rolling over and pushing up. However, the defect itself does not have prognostic significance.

Urinary tract

Abnormalities of the urinary tract are the major factors affecting the prognosis of patients with prune belly syndrome. Patients are at high risk for developing renal failure in infancy and childhood. As many as 39% of patients, typically those with impaired renal function at initial evaluation, develop chronic renal failure in childhood or adolescence, with 17% of them undergoing renal transplantation.[27]

Kidney

The kidney in prune belly syndrome has many ranges of disorders, from total agenesis (rare) or dysplasia to no significant aberration.[28–31] Ureterohydronephrosis occurs bilaterally in 98% of patients, while renal dysplasia is detected in 35%–50% of patients and renal scarring in an additional 38%.[27,32] The degree of renal dysplasia or hydronephrosis does not appear to be related to the degree of abdominal wall deficiency.

Ureter

The ureters are characteristically markedly elongated, dilated, and tortuous. The lower end of the ureter is more severely affected than the upper one, and there are occasional saccular dilatations of the middle segment. The orifices are usually patent, and obstruction is rare. Vesicoureteral reflux is common and present in up to 78% of patients, mostly bilateral (Figure 82.2).[27] The ureteric smooth muscle is replaced by fibrous tissue in the affected areas, and there is scarcity of muscle bundles on histologic examination.[33] Ehrlich and Brown[34] studied the structure by electron microscopy and reported a marked decrease in nerve plexuses with irregularity and degeneration of nonmyelinated Schwann fibers. These findings are in keeping with the poor peristalsis of the affected ureters.

Bladder

Bladder abnormalities are common in prune belly syndrome. The typical bladder is large, irregular in shape, and thick walled. Although the bladder wall is thickened, trabeculation is rare. Histologically, the intrusion of fibrous tissue between sparse muscle layers is similar to the ureters.[35]

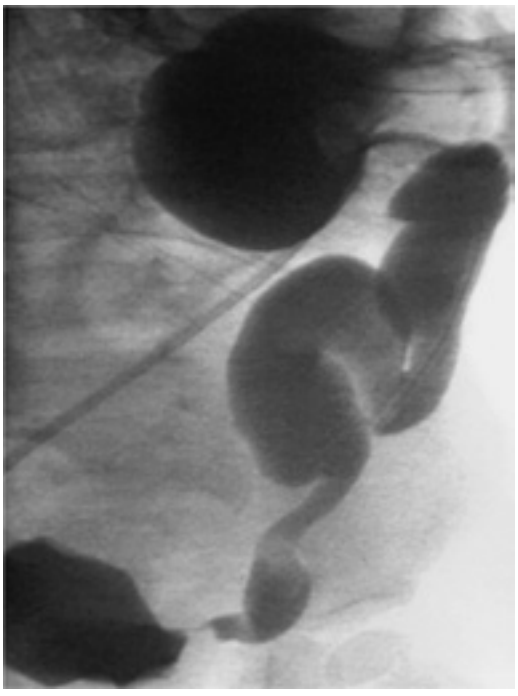

Figure 82.2 Micturating cystourethrogram showing Grade V vesicoureteral reflux into left dilated tortuous ureter.

Commonly, there is a patent urachus or urachal cyst. The trigone is surprisingly large, with very widely spaced, usually large and abnormal-appearing ureteric orifices, which can be expected to reflux. The bladder neck is often wide and ill-defined. Pelvic innervation and bladder ganglion cell distribution has been found to be normal.[28]

Urethra

A mildly dilated anterior urethra is the most common abnormality, present in 70% of patients with prune belly syndrome.[30] Both scaphoid and fusiform megalourethra have been found in association with prune belly syndrome but are rare.[36] The prostatic urethra is usually wide and elongated at the bladder neck (Figure 82.3). It tapers to a narrow point at the level of the urogenital diaphragm, even though most patients do not demonstrate true obstruction at this point.[30] Often, there is a posterior urethral diverticulum formed by a large prostatic utricle. The reduced musculature and prostatic hypoplasia cause a "functional obstruction" to bladder outflow.[3]

There are also reports of abnormalities of the penis, including ventral and dorsal chordee, hypospadias, and hypoplastic or absent corpora cavernosa.[30] Ejaculation is possible but usually is retrograde due to the open bladder neck.

Figure 82.3 Micturating cystourethrogram showing ill-defined bladder neck with enlarged prostatic urethra. No urethral obstruction was demonstrated in the 2-week-old infant.

In females, bicornuate uterus and vaginal atresia are the most common genital anomalies encountered. Six of the seven female cases reported by Reinberg et al.[8] had vaginal atresia or uterine duplication, and these frequently coexisted in the same patient. Other urogenital anomalies include urogenital sinus and ambiguous genitalia.

Testes

Bilateral cryptorchidism is an essential characteristic of prune belly syndrome. The testes may be located anywhere from just inferior to the lower pole of the kidney to near the ureterovesical junction.[31,35] Maldescent of the testes is believed to be related to the impaired contraction of the abdominal musculature and to the mechanical obstruction caused by an enlarged bladder and dilated upper tract.[36] The gubernaculum plays an important role during testicular descent, which has been explained mainly by its action for dilatation and contraction.[37] A recent structural study of the gubernaculum testis has demonstrated a predominance of collagen type III fibers and smaller elastic fibers in fetuses with prune belly syndrome compared to a predominance of collagen type I in controls. The authors speculated that the mechanical obstruction or the altered intra-abdominal pressure hinders gubernacular remodeling.[38]

In fetuses with prune belly syndrome, testicular histology revealed reduced spermatogonia and Leydig cell hyperplasia.[39,40] Testicular biopsy samples of infant testes in prune belly syndrome demonstrate atypical germ cells with large nuclei and prominent nucleoli, and intense alkaline phosphatase staining localized to the cytoplasmic membrane.[40] The similarity of histological appearance of these testes to those in intratubular germ cell neoplasia suggests that long-term follow-up of these patients for the development of invasive germ cell tumors is important. A few cases of malignancy in the testes of patients with prune belly syndrome have been reported.[41–43]

ASSOCIATED ANOMALIES

In the last 40 years, several reports have shown a constant association between prune belly syndrome and extragenitourinary anomalies, with the most frequent being orthopedic and gastrointestinal followed by cardiopulmonary and developmental.[44]

Orthopedic comorbidities have frequently been reported in 50%–65% of patients with prune belly syndrome.[44,45] The most common abnormalities are scoliosis, talipes deformities, pectus excavatum/carinatum, developmental dysplasia of the hip, and sacral agenesis. Awareness of this association is essential either preoperatively, as pectus deformities may restrict pulmonary volumes, or intraoperatively, as developmental dysplasia of the hip may limit positioning of the patient on the operating table.

Gastrointestinal anomalies are observed in 36%–63% of patients.[44] Constipation is the most common gastrointestinal condition and may be very difficult to treat because of

the lack of abdominal wall musculature. In a recent large cohort of living patients with prune belly syndrome, 58% of patients were diagnosed with constipation.[44] Due to the close anatomical and functional relationship between the gastrointestinal tract and the bladder, it is extremely important to treat the underlying constipation without delay. Malrotation of the midgut with a single mesentery and the occasional sequelae of volvulus and obstruction are found in approximately in 10% of patients.[44] Other gastrointestinal anomalies include intestinal obstruction, hepatoblastoma, gastroschisis, omphalocele, imperforate anus, Hirschsprung disease, and duodenal atresia.[44,46–49]

Cardiopulmonary anomalies have been described in 24%–49% of patients with prune belly.[44] Reactive airway disease and asthma affected nearly a quarter of patients, followed by pulmonary hypoplasia, patent ductus arteriosus, patent foramen ovale, atrial–ventricular septal defects, and pneumothorax.[44] The presence of cardiopulmonary comorbidities associated with the lack of abdominal wall musculature and limited movement of the diaphragm indicate that these patients require intraoperative antibiotics because of the increased risk of postoperative respiratory infections. In addition, micrognathia has been reported in patients with prune belly syndrome, which may result in difficulties with intubation.[50]

Neurologic anomalies have also been described in 20%–43% of patients, such as hearing loss, seizures, brain tumor, tethered cord, and spina bifida.[44]

Antenatal diagnosis

Antenatal diagnosis in the second trimester is the most common presentation of prune belly syndrome, with major renal tract abnormalities being diagnosed at as early as 13 weeks of gestation.[51] The sonographic features for the diagnosis of prune belly syndrome are bilateral hydroureter and hydronephrosis, a distended thick-walled bladder, and oligohydramnios. The differential diagnosis includes posterior urethral valves and megacystis microcolon intestinal hypoperistalsis (MMIH) syndrome. Differentiating between posterior urethral valve and prune belly syndrome could be difficult, as in posterior urethral valves, there is an isolated dilatation of the posterior urethra in association with a thick-walled bladder, leading to a keyhole sign. Conversely, MMIH syndrome is more common in females (4:1) and has several features in common with prune belly syndrome, such as hydronephrosis, a large bladder, and laxity of the abdominal wall musculature.[52] In addition, in MMIH, there are abdominal distension, incomplete intestinal rotation, microcolon, and decreased or absent intestinal peristalsis.[52]

Unfortunately, fetal detection of prune belly syndrome has not led to an improved outcome.[53,54] Fetal vesicoamniotic shunts have been used in the hope of preventing renal parenchymal damage in children with enlarged bladder and upper renal tract dilatation.[55–57] However, studies have failed to document a beneficial effect of fetal intervention on subsequent renal function.

POSTNATAL ASSESSMENT AND INVESTIGATIONS

The prune belly appearance of the abdominal wall together with bilateral undescended testes allows easy diagnosis of this condition in a newborn. The initial postnatal course is dictated by the severity of comorbidities, which are present in up to 75% of the patients.[28] The most common is prematurity, with 43% of infants born preterm.[36] Perinatal mortality rates range between 10% and 25% and are related to the degree of prematurity and to the presence of severe cardiopulmonary abnormalities.[36] The classification proposed by Woodard and Zucker[29] is based on prenatal and postnatal findings and divide the patients into three groups (Table 82.1): Children in group 1 have poor renal function and will usually die in the immediate postnatal period due to pulmonary complications. An aggressive surgical approach in these children should be avoided. Group 2 children have mild impairment of renal function and may progress to renal failure. Group 3 consists of the majority of children with prune belly syndrome, who have normal renal function and dilated renal tracts. When antenatal oligohydramnios is present, pulmonary complications should be anticipated, and an immediate chest x-ray to exclude pneumothorax and pneumomediastinum is necessary. Initial

Table 82.1 Woodard and Zucker classification of prune belly syndrome

Category 1 (20%)	Category 2 (40%)	Category 3 (40%)
Oligohydramnios	Typical external features	External features mild or incomplete
Pulmonary hypoplasia or pneumothorax	Hydroureteronephrosis	Stable renal function
Renal dysplasia	Mild or unilateral renal dysplasia	Mild uropathy
Urethral obstruction or patent urachus	Risk of urosepsis	
Club foot	Risk of azotemia	

Source: Hassett S. et al., Prune belly syndrome, *Pediatr Surg Int* 2012;28:219–228.

creatinine measurements reflect maternal renal function, and repetitive sampling is necessary. The measurement of the lowest creatinine level after 5 days of life (nadir creatinine) has been demonstrated to be a valuable predictor of renal failure in boys with prune belly. None of the 35 patients reported by Noh et al.[54] with a nadir creatinine <0.7 mg/dL and without urosepsis had renal failure. Conversely, 12 of 13 children (92%) with a nadir creatinine greater than 0.7 mg/dL went into renal failure. Urine should be checked for any infection and antibiotic prophylaxis to prevent urinary tract infection (UTI) started. Renal ultrasound will provide information regarding echogenicity of the renal cortex, presence of cysts, parenchymal thickness, corticomedullary differentiation, renal tract dilatations, bladder volume, and postmicturition residue. A micturating cystourethrogram (MCUG) will provide information regarding vesicoureteral reflux and the rare presence of posterior urethral valve or megalourethra. However, contrast medium should be sparingly used in the presence of poor renal function and impaired glomerular filtration rates to avoid rapid rise in serum osmolality and subsequent intraventricular hemorrhage. Diuretic renal scintigraphy, most commonly a mercaptoacetyltriglycine (MAG-3) scan, is indicated to assess drainage, while a dimercaptosuccinic (DMSA) scan is effective in identifying renal scars or dysplasia by the presence of photopenic defects. However, both modalities may have limitations due to the inability to characterize obstruction in dilated and poorly functioning kidneys.[32] The real challenge in patients with prune belly syndrome lies in the ability to differentiate a dilated unobstructed urinary tract from an obstructed system that will benefit from surgical intervention. In patients with inconclusive drainage patterns on MAG-3 scan, the use of magnetic resonance urography (MRU) has been recommended as a reliable method of assessing renal drainage.[58] In addition, MRU allows sufficient resolution to detect renal dysplasia and loss of corticomedullary differentiation.[59] On MRU, patients with prune belly syndrome also show a wide range of abnormal calyceal morphology, from absent or decreased number of calyces to blunted or widely distorted branching.[32] The main limitation to the use of MRU in children is the requirement of deep sedation/general anesthetics, its high cost, and the use of gadolinium-based contrast, which limits use to those with normal renal function, due to the reported risk of nephrogenic systemic fibrosis.[60]

A videourodynamic (VUD) study is often performed for preoperative planning or following recurrent UTIs. The VUD findings invariably show a large capacious bladder (2.4 ± 1.4 times for estimated bladder capacity for age), normal bladder compliance, and a large postvoid residue (mean 63%).[27]

MANAGEMENT

The surgical management of the urinary tract should be tailored to suit individual cases. The initial recommended strategy is directed at bladder drainage and prevention of UTI, assuming that the renal function will stabilize and renoureteral anatomy will improve spontaneously.[31,61] This approach requires close follow-up, long-term urinary surveillance, and regular imaging. Urinary tract reconstruction should be considered in the presence of obstruction, stasis, and dilating vesicoureteral reflux associated with UTIs as these represent common risk factors for progressive renal damage. The rationale for a conservative approach is based on a few studies that have demonstrated no changes in preoperative and postoperative serum creatinine levels after early ureteric reconstruction consisting of ureteric tapering, reimplantation and reduction cystoplasty,[62] no long-term reduction in bladder capacity or improvement in voiding dynamics after reduction cystoplasty,[63] and no difference in urodynamic profiles between reconstructed and nonreconstructed patients with prune belly syndrome.[64] In addition, upper and lower urological reconstruction carries a complication rate of up to 40%, with revisional surgery often required, most likely due to the muscular deficiency present in these patients.[62,65] Multiple surgical procedures are often necessary in children with prune belly syndrome, with a mean of >2 procedures per year,[27] which include the following:

Circumcision

Circumcision is commonly recommended in children with abnormalities of the urinary tract who are at increased risk of UTI such as posterior urethral valves (>50%), vesicoureteric obstruction (46%), high-grade vesicoureteral reflux (30%), and prune belly syndrome.[66] Circumcision, by reducing the periurethral colonization of UTI-forming organisms in infants,[67] has a biologically proven protective effect, which persists into preschool children and adults, with a 90% reduction in risk of developing UTI.[66]

Orchidopexies

Bilateral intra-abdominal testes are one of the defining features of the syndrome. Current guidelines of the American Urological Association recommend, in the absence of spontaneous descent by 6 months, that orchidopexy should be performed in the first 18 months of life to preserve available fertility potential.[68] When urinary or abdominal wall reconstruction is considered in the first year of life, bilateral orchidopexies can be performed at the same time. In approximately two-thirds of boys, the testicular vessels are of adequate length to allow the testis down into the scrotum, while in the remaining one-third, it is necessary to divide either unilaterally or bilaterally the testicular vessels for a Fowler–Stephens orchidopexy,[46] with success of 80% and 85% for single- and two-stage orchidopexy, respectively.[69] The laparoscopic approach is the procedure of choice for the management of intra-abdominal testes when no other abdominal procedures are planned. Technical considerations during a laparoscopy in patients with prune belly are related to air leak due the lax abdominal wall. It is recommended to make smaller port incisions and use higher CO_2

flow rate and longer instruments.[70] Higher rates of testicular atrophy have been reported in children with prune belly syndrome, ranging from 3% for the two-stage orchidopexy[71] to 30% in children older than 2 who underwent a single-stage orchidopexy (82%) or a Fowler–Stephens orchidopexy (14%) at the same time as the urological reconstruction.[62]

Urinary tract reconstruction

Upper or lower urinary tract reconstruction is indicated in the presence of obstruction, inadequate bladder emptying, dilating vesicoureteral reflux associated with recurrent UTIs, or worsening hydronephrosis on ultrasound or differential renal function on nuclear scan. Two large contemporary series of patients with prune belly have described unilateral or bilateral ureteric reimplantation in 41%–85% of patients, formation of appendicovesicostomy in 9%–35%, reduction cystoplasty/resection of bladder dome and urachal remnant in 9%–89%, formation of vesicostomy in 11%, and urethral surgery (dilatation or urethrotomy) in 13%. Less frequently, other urological procedures may be required such as pyeloplasty, nephrectomy, ureteroureteroanastomosis, nephrostomy, and tumor resection.[27,46]

Abdominoplasty

Several techniques have been described over the years for the abdominal wall reconstruction of patients with prune belly syndrome. In 1981, Randolph et al.[25] described the only technique that utilizes a U-shaped incision between the tips of the 12 ribs and advancement of the upper abdominal layers toward the groin and pubis. The techniques described by Ehrlich in 1986, Monfort in 1991, Furness et al. in 1998, and Lesavoy in 2012 have in common a medial advancement of the lateral musculofascial layers toward the midline in a double-breasted fashion using an intraperitoneal (Ehrlich, Monfort, Lesavoy) or extraperitoneal (Furness et al.) approach.[36,72] Other differences among these techniques lie in the elliptical excision of the excessive skin and in the incision of the musculoaponeurotic fascia (MAF; midline or lateral). An innovative technique has been recently described by Denes et al.,[65] which includes an elliptical xyphopubic incision, excision of the excessive skin and subcutaneous tissue, and preservation of the umbilicus as an island attached to the MAF. A single lateral elliptical incision of the MAF is made in the most lax side of the fascia, with creation of a wider or inner flap containing the umbilicus and a shorter or outer flap. The wider inner flap is sutured over to the parietal peritoneum of the shorter flap, while the shorter outer flap is sutured over the inner to the opposite side, therefore creating a double-breasted reinforcement of the anterior abdominal wall. The umbilicus is exposed through the buttonhole incision of the outer flap and fixed to the flap.[72] This technique has a good cosmetic and functional result, requires only one incision of the MAF, and allows access to the abdominal cavity with excellent exposure of the viscera. The benefits of abdominal wall reconstruction are well established, with increased patient self-esteem;[73] improvements in continence, sensation, and urinary flow; improved postvoid residuals; and reduction in defecation time.[74] These improvements are not correlated to the genitourinary reconstruction, and the authors speculate that they may be secondary to the increased intra-abdominal pressure of the Valsalva maneuver in accordance with the Pascal principle (pressure = force/area).[74] The timing of the abdominoplasty is still a matter of debate among pediatric urologists, with some authors recommending early[46] abdominoplasty and some later.[27] It is our practice to offer abdominoplasty before starting school, between 3 and 4 years of age.

LONG-TERM OUTCOME

Long-term follow-up studies have shown that adequate bladder emptying is observed in 48%–72% of patients. In the remaining children, the bladder is managed through clean intermittent catheterization, approximately one-third through the urethra and two-thirds through a Mitrofanoff channel.[27,46] Only a minority of patients will require either Crede or Valsalva maneuvers to ensure bladder emptying.[46] Between 11% and 39% of the long-term survivors will develop chronic renal failure as a result of renal dysplasia, recurrent pyelonephritis, or obstructive nephropathy, with approximately half of them undergoing renal transplantation.[27,46] However, good bladder emptying must be achieved prior to transplantation to avoid significant risk of infection in the presence of immunosuppressant therapy.

Conjoined twins

JUAN A. TOVAR AND LEOPOLDO MARTINEZ

INTRODUCTION

Genetically identical individuals joined by a part of their anatomy and often sharing one or more organs are known as *conjoined twins*. Total prevalence of this event has been estimated at 1.47 per 100,000 live births.[1] Forty percent of all are stillborn, and a further 30% die on the first day of life. Only 18% of all conjoined twins survive longer than 24 h, and they represent one of the more difficult challenges of pediatric surgery.[2,3]

Mythologic creatures like two-faced Jano or multiple-headed Hydra were probably inspired by observation of conjoined twins.[4] Although representations of conjoined twins from ancient cultures were relatively frequent, they became popular after the original Siamese twins Chang and Eng Bunker were sent to the United States in the nineteenth century for exhibition in a circus[5]; the term *Siamese twins* was coined as a reference to them.[6] The complexity of the technical problems involved in separations of conjoined twins explains why the first attempts are relatively recent (seventeenth century).[7]

ETIOLOGY

Conjoined twinning is due to incomplete division of a primitive embryonal disk destined to produce identical twins.[1,8] These are, of course, monozygotic, monochorionic, and isosexual, and share the same genome and fingerprints.[9,10] The causes for this incomplete division are unknown, but interestingly, two-thirds of the cases are females. Two opposing theories have been suggested to explain these phenomena. Some authors support a *fusion* process because, with the exception of parapagus, all types of conjoined twins can be explained by the fusion of two separated embryos.[1,11] This fusion theory could explain some ancient experiments in amphibians, and a few modern molecular genetic observations suggest that fusion of two originally separated embryos may be the explanation for some rare cases in which there is sex discordance.[12–14]

There are supporters of a *fission* theory, claiming that conjoined twins are the result of an incomplete split of the embryonic axis.[8,15] Spencer pointed out in her monography[16] that the twins are always joined by central parts of their anatomies and that they are always homologous in the sense that they never have the head or the lower limbs on opposite sides. This seems to confirm that the mechanism is a missed cleavage of the primitive embryonal disk along the longitudinal axis.

CLASSIFICATION

The location, extent and nature of the bridge between both twins vary widely, and this complicates description of the anatomy of each set. Several classifications attempt at simplifying description. Conjoined twins are always of the same sex and are joined homologously, i.e., chest to chest, abdomen to abdomen, pelvis to pelvis.[17] They can be divided into ventrally and dorsally joined and subdivided according to the level of fusion.[16,18] We divide them by taking into account their asymmetric or symmetric nature and the level of the fusion, followed by the suffix *-pagus*.

Asymmetric twins include *fetus in fetu*, *acardius acephalus*, and *heteropagus* parasitic twins. The adscription of the first variety of organoid teratomata to the family of conjoined twins is only acceptable when they are "organoid" and contain a more or less rudimentary spine.[19] *Acardius acephalus* is a variety of parasitic twin devoid of heart and head that is connected by marginal placental vessels with the healthy twin (the *autositus*), who is in charge of circulation and nutrition of both.[20] *Heteropagus* twins are usually attached to the abdominal wall of an anatomically normal *autositus* twin, without or with exomphalus, as organoid parasitic masses containing various organs and limbs unable to sustain independent circulation by themselves.[21,22]

Symmetric conjoined twins may be joined by the head (*craniopagus*), the thorax (*thoracopagus*), the abdomen (*omphalopagus*), the spine (*rachiopagus*), or the caudal pole (*ischiopagus* and *pygopagus*). Occasionally, they are laterally fused along the body axis (*parapagus*).[23–25]

CLINICAL PRESENTATION

Nowadays, most conjoined twins are prenatally diagnosed by ultrasound (US) in advanced countries, preventing serious obstetric problems. Except in thoracopagus with common heart and in asymmetric twins, both fetal heart tones can be identified like in regular twins. The heads and the limbs of conjoined twins are on the same side (homologous), in contrast with regular twins, which are usually arranged in opposite directions. This allows fetal ultrasonographic diagnosis that leads to detailed US and/or magnetic resonance imaging (MRI) studies aimed at defining the anatomy of the fusion and the chances of separation.[25–27] MRI has been used more commonly in recent years to confirm the diagnosis and to define the nature of joining. Ultrafast T2 sequences eliminate the need for maternal sedation and allow precise anatomical assessment.[25] Accurate prenatal diagnosis is critical because it allows optimizing the outcome of the twins. The parents should be referred to a fetal center, and they are entitled to receive counseling by a multidisciplinary team.[2] Craniopagus and those with a sole cardiac mass or complex cardiac connections have the worst prognosis. Usually, parents are offered termination of pregnancy, an option that is chosen by 50%–70% of them when available.[28]

There are increasing risks of preterm birth, so in most cases, labor will be expected around 35 weeks of gestation. Although vaginal delivery has been reported, it is usually associated with obstetric trauma: long bone fractures, rupture of exomphalos, etc.[29–31] Most sets of twins are delivered by Cesarean section and can be taken care of by interdisciplinary teams from the beginning. The staff present at birth should be divided into two teams, one for each baby. Each person should know his or her place and role. Transfer and resuscitation of the twins require a specially designed platform than allows access from all sides.[2]

The anatomy varies widely according to the modality of joining. Thoracopagi with common hearts have almost constantly severe cardiovascular and arterial anomalies that produce early symptoms and may be rapidly lethal.[32,33] The most frequent forms, omphalopagi and thoracopagi, often have an omphalocele membrane as a part of the joining bridge (Figures 83.1 and 83.2). The livers are often fused, and the intestines are usually connected or shared. The bladder may be common and sometimes opens at the lower part of the bridge as an exstrophy (Figure 83.3). In cases joined by the rump (Figures 83.4 and 83.5), the anatomical varieties in terms of gastrointestinal (g.i.) and urogenital openings are multiple.

Serious malformations or trauma suffered by only one of the twins may create difficult clinical situations because crossed circulation creates a single internal environment, which is hard to manipulate: the healthier twin can compensate in part for the problems of the diseased one, but the latter may expose the former to disbalances, toxins, or medications.[34]

DIAGNOSIS

A comprehensive understanding of the anatomy of the organs and the distribution of their functions is necessary for planning viable separation strategies. The imaging investigation should be as extensive as possible. It aims to delineate anatomy, to assess the choice of separation, and finally, to counsel

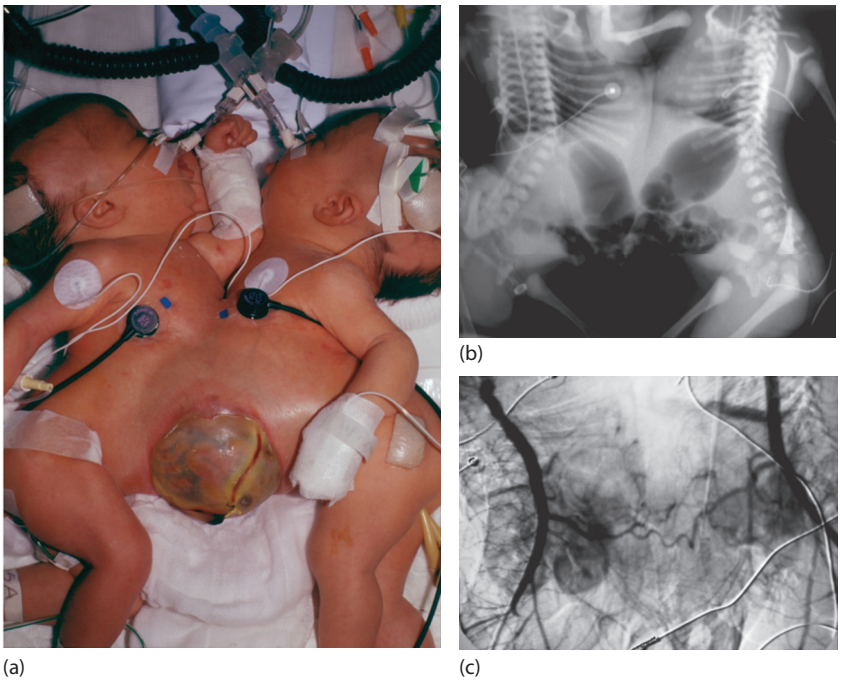

Figure 83.1 **(a)** Set of omphalopagus twins. Severe brain hemorrhage in twin on the right after vaginal delivery prompted neonatal separation. Only the twin on the left survived. Neonatal investigation demonstrated **(b)** two separated hearts and **(c)** an abdominal arterial communication between the twins.

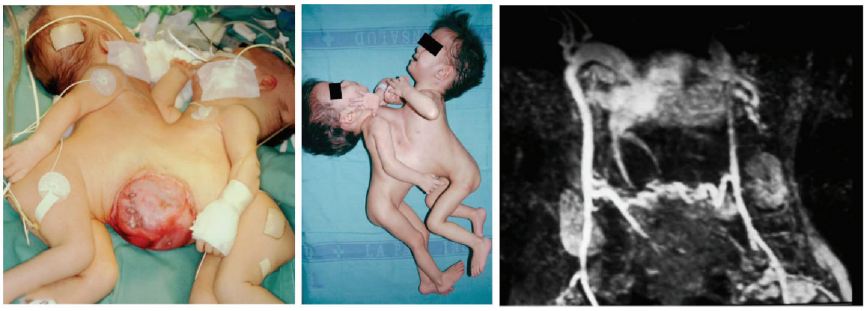

(a) (b) (c)

Figure 83.2 Two sets of thoracopagus twins with common heart. **(a)** Separation was undertaken only in the first set because only a narrow atrial bridge joined them; unfortunately, the twins did not survive. **(b)** Separation was considered impossible in the second set; they shared a common heart, had a gross arterial communication at abdominal level, and **(c)** the twin on the right had an hypoplastic aorta.

(a) (b) (c) (d)

Figure 83.3 **(a)** Omphalopagus twins with incomplete cloacal exstrophy that was prenatally diagnosed. **(b, c)** The single bladder opened under the exomphalos. **(d)** A single colonic opening was visible in the middle of the bladder plate. Both had anorectal agenesis with one single urogenital canal and double uteruses and vaginas. Separation involved division of the colon with colostomies, and bladder closure. Later on, sagittal anorectoplasty with colonic and vaginal pull-through was performed.

parents about prognosis.[35] Plain x-rays and g.i. or urogenital tract contrast studies may depict the points of junction and other features of the corresponding organs, but due to the atypical anatomy,[36] incomplete understanding leads to unexpected surprises. Ultrasonography helps at every diagnostic step.[27,37] Angiography, which was widely used in the past for depicting the nature of the blood supply of the shared organs (Figure 83.1),[38] is being replaced by computed tomography (CT) or magnetic resonance (MR) angiography, which are now considered the best ways of depicting the vascular arrangement (Figure 85.2).[35] MRI better depicts the fused neural and meningeal tissues in craniopagus, rachiopagus, ischiopagus, pygopagus, and parapagus.[39] Both CT and MR are crucial for imaging the anatomy of conjoined hearts.[40] Helical CT reconstruction of the bony junctions may help in preparing strategies of skeletal separation (Figures 83.4 and 83.5).[41] Nuclear imaging may help to define the functional anatomy of the liver, kidney, and other organs.[42]

Hematologic and biochemical studies are often misleading due to the situation of cross-circulation. When the vascular channels are large, *parabiosis* is complete, but when only minor territories are in connection, both twins maintain some internal environmental differences that can be relevant in cases in which blood tests are necessary for diagnosis. Other tests, like electrocardiogram (ECG), are challenging when the hearts are connected.[43] Metabolic rate may show considerable differences between twins upon calorimetry.[44]

TREATMENT

Preoperative ethical issues

The principles that regulate the medical profession are particularly difficult to respect in conjoined twins, and serious ethical dilemmas are to be expected[26,45,46]:

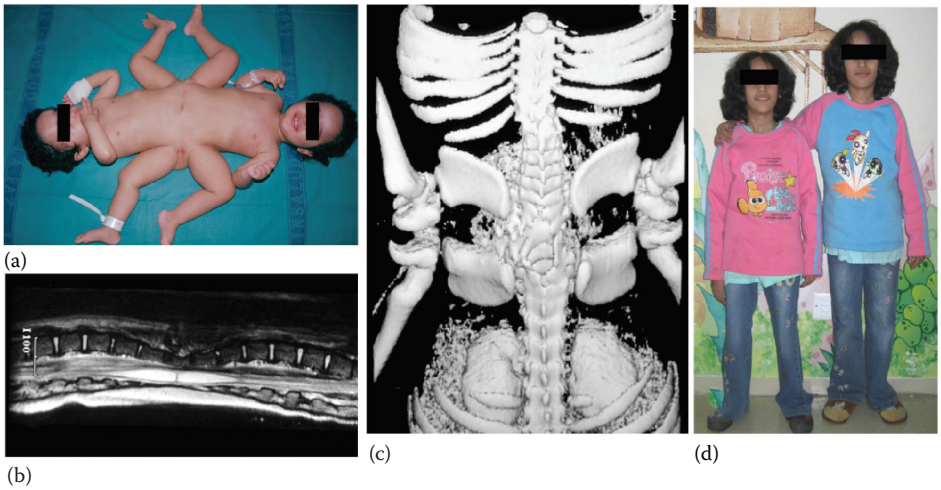

Figure 83.4 **(a)** Ischiopagus tetrapus (four legs) twins. **(b, c)** The spines and the spinal cords were joined at the caudal end as shown by helicoidal CT reconstruction. During separation, the spines were divided, the meningeal sacs were reconstructed, a quadruple iliac osteotomy was performed for joining both pubic bones in each twin, the urogenital system was reconstructed, and colostomies were fashioned. **(d)** Patients at the age of 12: they deambulate normally and enjoy relatively normal lives with permanent colostomies and intermittent bladder catheterization.

Figure 83.5 **(a)** Caudal parapagus tripus twins with an extra thoracic limb irrigated from the abdominal aorta of the twin on the left. **(b)** There was a single pelvis with two lower limbs and two spines with communicating spinal canals and joined cords. Separation involved two surgical steps. First, the spinal cords and meningeal sacs were separated and subcutaneous expanders were inserted. Secondly, the sacrum and the g.i. and g.u. tracts were divided, and the parietal defects were closed. In twin A, the skin and muscle of the additional limb were used as a vascularized flap. In twin B, a synthetic mesh was used for this purpose. Colostomies were fashioned. **(c, d, e)** Both twins are able to deambulate with braces.

The principle of *autonomy* (the decisions of the patient should be respected) is usually exerted by proxy by the parents in children, and this may be a source of conflicts among them or with doctors or the courts if unanimous decisions are not agreed upon.[47]

The principle of *justice* (similar chances for both patients) is obviously at risk when it comes to separation that may involve mutilation or sharing of organs.

The principles of *beneficiency* and *nonmaleficiency* (the benefit of the patients should be sought and no harm should be inflicted on them), which are considered as the ethical backbone of the medical decision-making process, are also difficult to apply if separation is necessary for the survival of only one twin, if distribution of organs is uneven, and if separation involves, as is usually the case, loss of some functions that might be preserved without separation.

When separation of conjoined twins is considered, the patients are usually too young to decide by themselves, the parents are heavily influenced by information delivered by doctors, and the team involved is usually so large and often ethically discordant that keeping a unified line of decision becomes difficult. Acknowledgement of a strong moral leadership after open discussion of every issue is required before providing to the parents information about the chances and the consequences of separation. In case of serious discrepancies among all participants in the process of decision, the courts might be involved.[48,49]

Furthermore, new difficulties may arise due to interference of the media, which is difficult to avoid in cases in which so many people are involved. The twins and their family should be protected from these agents, and if possible, the entire process of decision making and even the separation should be kept private.

Preoperative meetings

When separation has been decided, one or more meetings with scrub nurses, nurses, anesthesiologists, and surgeons of the required specialties (general pediatric, orthopedic, plastic, urologic, neurologic, and cardiovascular surgery) should be scheduled.[50] Technical aspects should be discussed, and the operation itself should be rehearsed because installation of the set of twins on the table, skin prep and draping, and transport of one twin with the corresponding anesthetic equipment to another table for reconstruction after separation should be carried out according to a previously established protocol. The expected order and extent of the participation of each specialist team in the separation should be scheduled as well. Everybody has to be clear on his/her exact role. The surgeon in charge of the direction of the operation acts as an orchestral conductor, and his/her coordinating activity extends well beyond the end of the separation itself. It should be kept in mind that, despite extensive previous investigation, some abnormalities will be encountered unexpectedly during operation.[51,52]

Separation

Anesthesia is a serious challenge not only because of the obvious anatomical difficulties for intubation, insertion of lines, and invasive monitoring but mainly because of the previously mentioned situation of *parabiosis* in which one single internal environment is shared to variable extents by the twins.[53] Anesthetic procedures require meticulous planning, simulation of different scenarios, and a close team work.[54] In most cases, twins require anesthesia for both diagnostic and surgical procedures prior to separation, and this should allow gaining experience before the separation.[53] Anesthesiologists should be especially aware of the difficulties of airway management, keeping intravascular volume, control of temperature, and unusual positioning of the twins. The drugs administered to one pass on into the other one, and biochemical and gas monitoring may be confusing.[55–57]

Asymmetric conjoined twins represent, in general, surgical challenges that are not unlike other ones met in this specialty. The *acardius acephalus* parasitic twin is inviable and dies upon clamping the umbilical cord of the host (autositus) twin. The *fetus in fetu* is treated as a tumor, and *heteropagus* asymmetric parasitic twins are removed with attention to preserving as much tissue as possible in order to respect the organs and allow wall reconstruction of the host.

If possible, separation should be postponed several months to allow the best possible imaging and a careful planning of surgery. Neonatal or early separation is only indicated for life-threatening reasons (for instance, one twin may be very ill or develop intestinal obstruction).[52,58,59] At this age, mortality is higher than when most anatomical and functional features of the set have been ascertained and appropriate planning has been completed. However, approximately one-third of conjoined twins require emergency procedures at birth.[52,60,61]

The separation of *craniopagus* may be extremely difficult or even impossible given the complexity of the neural, arterial, and venous connections involved. Modern imaging and sophisticated neurophysiologic monitoring are particularly useful in these cases. The final amount and nature of the brain tissue and the vascular network shared by the twins set the limits for separation.[8,62–65]

Separation of *omphalopagus* twins involves variable difficulties depending on the extent of organ sharing. These twins have, more often, fused livers and g.i. tracts. A small liver bridge without major vascular connections is relatively easy to take down, but a large mass of anatomically atypical liver with wide arterial, venous, and biliary connections[51,66,67] may be a serious undertaking. Perioperative ultrasonography and parenchyma-dividing devices used for liver resection are very useful for this purpose. The most common form of g.i. tract connection involves fusion of the small bowel from the upper jejunum down and divergence near the distal ileum. Separation consists, in most cases, of allocating half the available gut to each twin.

Additional problems may be met when atresia of one of the tracts or a common cystic dilatation of the mid bowel is present.[23,24,26,68,69]

Thoracopagus twins without connected hearts are separable, in contrast with those with a common myocardium. Only a few of them are amenable to surgery under cardiopulmonary bypass. In addition, these twins often have cardiovascular defects that may further complicate or preclude the separation. The aorta and the pulmonary arteries may be hypoplastic, and thick collaterals often largely connect the infradiaphragmatic aortas. Of those who cannot be separated, most die of the associated heart dysfunctions in the first months or years of life.[32,70]

Rachiopagus, *ischiopagus*, *pygopagus*, and *parapagus* twins share, to different extents, parts of the spine, central nervous system, and g.i. and genitourinary (g.u.) tracts, and they may represent formidable challenges. The separation of the bony parts requires highly skilled orthopedic surgeons. In some cases, the reconstruction of the pelvic rim requires bilateral iliac osteotomies and pubic fixation. In some cases, even refashioning a bony pelvis is impossible, and the subsequent prosthetic treatment is difficult.[71,72] The spine often has some malformations at other levels, and scoliosis has to be taken into account during follow-up.[73–75]

Neurosurgical separation may involve dividing a common spinal cord with reconstruction of the dural sacs on each side.[72,76] Since fusion of neural tissue is usually distal, the motor and sensitive effects tend to be limited.

The partition of a shared lower g.i. tract between both twins entails the loss of continence for one or both of them. In frontally joined twins, there is usually ileal confluence near the ileocecal valve and a single colon. The functional reconstruction of the pelvic organs is therefore rarely possible. Seldom, the rectal function can be preserved in one twin, but more often, this is impossible, and ostomies have to be fashioned at some stage. All refinements of advanced bowel management are necessary to obtain subsequent adaptation of these patients to a more or less normal life.[71,77]

The same can be said about distributing the urogenital tract structures between the twins. Keeping a bladder and urethra for one twin is rarely possible in most frontally united sets. Again, all refinements of reconstructive urology, bladder augmentation, clean intermittent catheterization, and continent urinary diversion may help to readapt these patients.[78–81] The native genital tract can be reconstructed if duplicated, but sometimes, vaginal replacement is necessary.

One of the major technical problems posed by separation of conjoined twins is the coverage of the huge parietal defects left. When only one survives, part of the wall of the other one can be used to bridge the defects, but in other cases, the skin can be expanded with subcutaneous expanders prior to separation,[82–84] and various flaps or biologic[85] or synthetic materials[86,87] may be necessary. Some authors, however, did not find any need for them to achieve a successful closure of large defects.[50,51] Since they have to be inserted in contaminated operative fields, the risks of bacterial colonization and infection are increased.

COMPLICATIONS

The nature of these risky operations involves a large number and variety of possible complications. Peroperative hemorrhage and damage to vital structures are always possible due to the often atypical anatomy. Bone division or meningeal membrane opening simultaneous to g.i. or g.u. procedures increases the risk of serious infection. Wound closure avoiding compartment syndrome may necessitate synthetic materials that are also exposed to contamination. Wound disruption and infection are therefore not rare. Finally, a wide range of complications not unlike those seen after other major operations may occur: internal hemorrhage, abscesses, vascular thrombosis, or postoperative intussusception, among others, are possible.

EARLY AND LONG-TERM RESULTS

Overall mortality in conjoined twinning is high. When diagnosis is made during early pregnancy, interruption of gestation is common practice in developed countries particularly for the forms with bad prognosis.[2,28,88,89] Fetal mortalities or stillbirths are also frequent. Obstetric mortality or severe birth trauma remains a real risk when prenatal diagnosis was missed, and this happens more often in undeveloped countries in which pregnancies are not monitored.[90] Up to 65% of the twins have associated anomalies involving various systems, the most common being cardiac defects, intestinal atresia, omphalocele, anorectal malformation, and spinal cord anomalies, that can cause demise in the first hours or days of life.[8,25] Thoracopagus twins with a common heart rarely survive because most have severe malformations. Of those sets in which separation is attempted, only a few individual twins survive.[33,91,92] However, thoracopagus without a shared heart can be successfully separated.

Most omphalopagus twins can be separated and survive if no obstetric trauma or severe associated malformation is present. In all other forms of conjoined twinning, a high proportion of the twins can be separated and survive, although with more or less extensive deficits that require follow-up for life and often additional operations.

In the long term, separation of conjoined twins rarely produces independent individuals without sequelae. Some cases of asymmetrical twins and onphalopagi may survive separation facing a normal life. Most other cases keep orthopedic or neurologic sequelae or have fecal and urinary continence problems that become predominant problems with the passage of time. Orthopedic and motor deficits may require prolonged rehabilitation and/or prosthetic appliances.[76,93] Permanent enterostomies are not rare, and the most sophisticated procedures for obtaining urinary continence or dryness are necessary.[23,75,80,81,94,95]

It is particularly discouraging that these pregnancies are often terminated in advanced medical and social environments able to provide lifelong assistance for rehabilitation and social integration, whereas twins from less privileged countries that are diagnosed at term and eventually separated lack all the necessary facilities. Reports on the long-term results usually describe sets of twins doing well with optimal social and psychological adjustments, although many of them require lifelong medical follow-up and care due to severe disabilities.[72,75,80]

Separation of conjoined twins is a major test for the quality of pediatric surgical care. Only institutions with highly sophisticated pediatric surgical specialties can undertake these operations with a reasonable chance of success. A careful study of the lessons learned from the experience of these selected centers is mandatory before any attempt at separation is undertaken.

Epidemiology and genetic associations of neonatal tumors

SAM W. MOORE

INTRODUCTION

Almost 50% of childhood cancer occurs under the age of 5 years[1] with clear evidence of inheritability being identified in many.

An interesting group of tumors are those occurring at birth or in the neonatal period because of the limitations of exposure to environmental factors—the so-called neonatal tumors (NNTs). NNTs include those tumors identified at birth (congenital tumors) as well as those identified during the first 28 days of life. Benign tumors and masses are not uncommon in this period, but malignant tumors, on the other hand, are uncommon, representing only 2% of childhood malignancies.[2]

It would appear necessary to define NNTs as benign or malignant. Benign tumors should probably include conditions like hamartomas, hemangiomas, lymphangiomas, and melanocytic nevi in a separate subsection. In addition, other causes of masses (e.g., abdominal masses related to the genitourinary tract, etc.) should be excluded.

Although benign tumors are not uncommon, they may be life-threatening because of their site and potential complications. They may also display variable behavior in the neonate and certain tumors [e.g., neuroblastoma, congenital fibrosarcoma (CFS)], although, having a malignant histological picture, may behave relatively benignly and even mature in the neonatal period. In addition, certain apparently benign neonatal masses (e.g., teratoma) may undergo malignant change if untreated.

Most neonatal tumors originate from mesodermal tissue with approximately 50% being present at birth (or antenatal diagnosis), with a further 20%–30% identified within the first week of life and the remainder within the rest of the neonatal period.[3]

The hypothesis that tumors (and even adult cancer) may be linked to or even initiated during fetal development[4–6] is supported by an ever-increasing number of animal experimental studies. This makes the study of NNTs particularly interesting, as a possible explanation of their early (as opposed to later) appearance may lie in the developmental processes still active in the host. However, the placenta forms a barrier to malignant cells preventing crossing from the mother to the fetus, thus protecting the fetus. Nevertheless, genetic or environmental (e.g., nutrition and exposures to environmental toxins/radiation) factors (or both) may still act as oncogenic promoters during gestation.[7]

This hypothesis is currently supported by an ever-increasing body of evidence and places the emphasis firmly on the developmental period as a focus of disease prevention and intervention. In this context, tumors occurring in the developmental and perinatal period can be regarded as a "window of opportunity" in cancer research[8,9] and may lead to the identification of potential therapeutic molecular targets.

Many of these tumors respond to therapy and have a good prognosis overall. The mortality rate for NNTs is estimated to be 6.26 per million live births.[10,11] Management of these tumors often involves the entire oncology team including neonatologists, radiologists, pediatric surgeons, pathologists, hematologists, and oncologists.

INCIDENCE OF NNTs

NNTs or perinatal tumors comprise only 2% of childhood malignancies. From an epidemiological point of view, however, there is little clarity as to the real prevalence, sites of origin, and pathological nature of NNTs, and reported series vary from unit to unit (Table 84.1), varying from 17 to 121 per million live births (Table 84.2).[12–18] Overall, the highest incidence has been reported in Japanese children and the lowest in black children in the United States.[1] The reported incidence in the United Kingdom and the United States,

respectively, is approximately 1 in every 12500–27500 live births.[2] The Manchester Children's Registry estimated the incidence to be 121.29 per 10^6 child-years when all children under 1 year of age including those with leukemias and lymphomas are counted.[14]

One of the difficulties in assessing the true incidence of NNTs is the fairly frequent nonreporting of tumors occurring in stillborn babies and babies dying in the neonatal period.

AGE AND SEX

The majority of tumors are diagnosed when the infant is between 1 and 4 weeks of age. Fewer malignant tumors are diagnosed at birth, although benign or potentially malignant tumors are frequently encountered then.

The male-to-female ratio is equal in the majority with the exceptions of retinoblastoma (male preponderance) and teratoma (female preponderance).

[c] <3 months.

PRENATAL DIAGNOSIS

With the advent of routine prenatal ultrasonographic screening and the considerable recent advances in technology, many NNTs are now diagnosed antenatally. This is particularly true of patients with renal masses/tumors, mixed germ cell tumors of the sacrococcygeal region, as well as masses in other parts of the body.

The advent of neuroblastoma screening programs brought more tumors to light but did not appear to affect the overall prognosis. The reason for this is that although the histopathologic features were that of neuroblastoma, the biological characteristics of neuroblastomas detected by screening in Japan, for instance, have been shown to be mostly favorable with a few having N-myc amplification.[41] As a result, the great majority improve spontaneously and disappear, but not all, as 10%–20% have unfavorable histological features and may progress.

CLINICAL PRESENTATION

Many NNTs present with benign masses, some of which may be incidental findings or diagnosed with antenatal ultrasonography. However, the clinical behavior may vary, and 34% of the 192 patients reported by the International Society of Pediatric Oncology from 12 different centers presented with metastatic disease.[14]

PATHOLOGY

A particular problem exists in classifying NNTs in that histological features of malignancy do not always correlate with clinical behavior. As a result, there are at least four clinical groupings of NNTs[20,27]:

1. Tumors that are clearly malignant by all the usual criteria but
   a. Behave more like those occurring in older children
   b. Behave better than expected
   c. Behave worse than expected
   d. Demonstrate unpredictable or uncertain behavior
2. Tumors that show local invasiveness but have no metastatic potential
3. Benign tumors that are either
   a. Life-threatening because of size and location
   b. Have a known tendency toward malignant transformation
4. Extreme rarities, e.g., malignant carcinomas that are similar to adult-type tumors

TUMOR TYPES

True carcinoma as seen in adults remains extremely rare in childhood, making up only 1%–2% of patients.[42] Instead tumors arising from mesenchymal tissue remain the most frequent.

The distribution of the various histological types of tumors appears to be relatively constant when compared with other published series (Table 84.3). In a study of 192 cases collected from 12 different countries by the International Society of Pediatric Oncology (1987–1991), 33 different types of tumors were reported to occur within the neonatal period.[27] Teratoma is the most frequently encountered type in our own[25] as well as other large series,[23,27] and is followed by neuroblastoma, leukemia, and soft tissue tumors (STS). Certain tumors (e.g., retinoblastoma and brain tumors) vary in incidence depending on hospital referral patterns. Renal and liver tumors occurred less frequently in the neonatal period.[14] Other types of tumors tend to be rarities.

ETIOLOGY AND CARCINOGENESIS

The etiology of cancer in children is multifactorial and probably includes both genetic and environmental factors. It would appear that these tumors are initiated early in fetal development and therefore have a short window of exposure to any potential environmental interference. It therefore would appear that genetic factors predominate in their etiology and pathogenesis. This may involve a fairly straightforward genetic defect in heritable tumors, whereas a more involved multistep process is probably involved in those occurring spontaneously.

Genetic factors in NNTs

Following the first report of the Philadelphia or Ph1 chromosome,[43] in affected cells of patients with chronic myeloid leukemia, genetic mechanisms have been implicated in the etiology of many cancers, thus opening new areas for diagnosis and prognosis. Tumors are accepted as being a largely genetically based disorder at the cellular level and have been implicated in both nonhereditary and hereditary forms of malignancy in children and adults.[44] This is particularly true of NNTs where most cancer cells are monoclonal and have a high incidence of chromosomal changes and some specific genetic mutations, as well as a clear inherited predisposition to malignancy.

As such, NNTs provide a unique opportunity to study familial and genetic associations because minimal interactions between genetic and environmental factors have occurred that soon after birth. Modern genetic surveillance techniques offer potential opportunities for prevention, in contrast to most malignancies encountered in older patients.[45]

A distinction between germline and somatic gene changes should be borne in mind, however, especially in interpreting the findings. By way of example, constitutional genetic mutations have been reported in 10–15% pediatric cancers. In neonates, these include trisomies 13, 18, and 21. In the case of trisomy 21, there is an increased association with leukemia and retroperitoneal teratoma, but other solid tumors like neuroblastoma are extremely rare.[46] In addition, the X-linked syndromes like the Klinefelter (47XXY) syndrome is associated with an increase in germ cell tumors, although once again, the prevalence of neuroblastoma is decreased.

Apart from explaining how tumors may present in the perinatal period, genetic control may also partly explain the variable behavior of certain tumors within the perinatal period.[9]

There are essentially *three groups* of genetic abnormalities involved in the epidemiology of NNTs:

1. Genes resulting in a high risk of malignancy (e.g., in retinoblastoma)
2. Genetically determined syndromes where an increased risk of malignancy exists
3. Genes that confer a higher risk by conferring an increased susceptibility to environmental factors

The frequency with which each occurs will be influenced by their incidence in the population/family at risk.

Genes resulting in a high risk of malignancy

Accumulating research over the past two decades has seen many significant advances in understanding the mechanisms of the heritability of cancer (5%–10% of all cancers). This is of particular interest in the field of NNTs.

The best example of this group is the RB1 gene, which confers a risk of retinoblastoma. Other examples include Li–Fraumeni syndrome, where there is an association of rhabdomyosarcoma (RMS), STS, breast carcinoma, adrenocortical carcinoma, brain tumors, and leukemia.

As many of the genetic mutations associated with malignancy in children appear to occur spontaneously, a double "hit"[47] or multigene etiology is a likely mechanism.

The "two-hit" or multistep model of tumor development

Whereas it is generally recognized that tumors are a genetically related disease, tumorigenesis can mostly be attributed to a multistep process, whereby each step probably correlates with one or more distinct genetic variations in the major regulatory genes.

Current understanding of this process began when Knudson,[47] in an attempt to understand the pathogenesis of

neonatal retinoblastomas, proposed that the tumor resulted from a combination of a prezygotic (germinal) mutation as well as a postzygotic (somatic) event. His so-called "two-hit" theory, based on extrapolated statistical data, was later confirmed by Comings[48] who suggested that both of these events could apply to mutations of the RB1 gene.

This "two-hit" model has evolved into a widely accepted multigene or multistep model. It is particularly applicable to inherited cancer models (and possibly neonatal tumors), whereby an inherited susceptibility occurs on the basis of an identified germline mutation that results in tumor development caused by further inactivation of a second allele (often tumor suppressor genes), which gives rise to early activation of the oncogenic pathway.

This theory provides the basis for understanding the pathogenesis of a number of tumors occurring in the neonatal period and has since been validated for a number of other tumor types (e.g., retinoblastoma, Wilms' tumor [WT], neuroblastoma, and other tumors).

In sporadic tumors (as opposed to hereditary tumors) a multistep process is more likely. The initial mutational activation of an oncogene is often correlated with nonmutational inactivation of tumor suppressor genes. As this is probably an early event, it is then followed by a number of independent mutations in other genes to allow neoplastic growth.

How this applies to special circumstances such as neonatally occurring tumors outside of these known examples is still unclear. These tumors have a number of host-specific features that include the potential of spontaneous regression in some, a greater capacity for cell repair, as well as a comparatively good prognosis when compared to histologically similar tumors occurring later in childhood. It is therefore reasonable to assume that further study of the genes controlling childhood cancer and particularly cancer occurring early in life warrants further attention.

Childhood tumors arising from a developmental progenitor cell may also differ from tumors occurring in adults. Because cancer results from multiple aberrant genetic influences on the cell cycle, the cancers of childhood (as well as a number of adult cancers) may be related to prenatal development. This new paradigm of thinking has led to a concept called "the developmental basis of health and disease."

Mechanisms whereby genes may initiate malignancy include

- Oncogene activation
- Inactivation of tumor suppressor genes
- Epigenetic factors

In other words, the activation of receptors then alters gene expression and triggers signaling cascades, which then affect transcription factors.

This must take into account factors that affect gene expression in addition to genetic mutations. This process is controlled by further regulatory genes, transcription factors, and signaling proteins.

A variety of host-specific features that may influence NNTs include spontaneous regression and a greater capacity for cell repair.

The fairly good prognosis of NNTs may be reflecting the possibility that critical signaling pathways are still active in the neonatal period.

On the other hand, the malignant potential of certain tumors (e.g., sacrococcygeal teratoma) has also been shown to increase with time.

Genetically determined high-risk syndromes

The identification of a genetic association of a specific tumor may be hampered due to the fact that the precise genetic mechanisms may not be recognized by the current genetic testing methods. Etiological factors involved in the pathogenesis of certain tumors (e.g., WT) appear to be more complicated than those of others (e.g., retinoblastoma).

Increases in familial occurrence or an increased risk in monozygotic twins may be present, and an association between a specific malignancy and a set of alleles at a specific locus is thus identified. This may not be exclusive to the particular tumor under study and may be associated with the pathogenesis of other types of tumors. Examples of this are the associations between leukemia, lymphomas, central nervous system neoplasms, and STS, as well as the RB1 and WT1 genes, among others. The evaluation of clinical associations and syndromes linked to specific tumor types is therefore of considerable importance.

Mendelian single-gene-related syndromes

Syndromes arising from defects in chromosomal breakage or disorders of sexual differentiation may lead to malignancy. A number of examples of Mendelian single-gene malignancy-related syndromes are described in Table 84.4.

These may be autosomal dominant, recessive, or X-linked. In addition, certain disorders of sexual differentiation may also be associated with cancer in the pediatric age group. Autosomal dominant syndromes include familial colonic polyposis, neurofibromatosis, and the nevoid basal cell carcinoma syndrome (Gorlin syndrome), as well as the blue rubber bleb and Sotos syndromes. Skeletal abnormalities such as multiple exostoses, polyostotic fibrous dysplasia, and Maffucci syndrome are also associated with a higher incidence of tumor formation. These tumors do not normally present in the neonatal period and are added for completeness, but are extremely interesting from a genetic point of view (i.e., in tracing the affected individuals in family groups).

Autosomal recessive syndromes associated with tumors include xeroderma pigmentosum, Fanconi anemia, Bloom syndrome, and ataxia telangiectasia syndromes. Bloom syndrome includes sensitivity to ultraviolet light, growth retardation, and immunodeficiency that is related with a higher rate

Table 84.4 Inherited syndromes and childhood malignancy

Chromosome Breakage Syndromes
Bloom syndrome
Fanconi's anemia

Neurofibromatosis
Tuberous sclerosis
Turcot's syndrome
Multiple mucosal neuroma syndrome
Basal cell nevus syndrome
Metabolic Disorders
Tyrosinemia (hereditary)
Alpha-1 antitrypsin deficiency
Glycogenolysis (type 1)
Immune Deficiency Disorders
Sex-linked lymphoproliferative syndrome
Wiskott–Aldrich syndrome
Severe combined immunodeficiency
Bruton's agammaglobulinemia

of associated malignancy occurring at an earlier age,[49] e.g., leukemias and gastrointestinal malignancies. Fanconi's anemia is also linked to leukemia and liver tumors. Tumors associated with an autosomal recessive familial inheritance as well as those associated with immunodeficient X-linked recessive syndromes occur outside of the neonatal period, suggesting some degree of an initiating environmental influence.

The Epstein–Barr virus has been suggested as a possible pathogenetic factor[50] in the X-linked lymphoproliferative syndrome. Of particular interest are the fragile chromosomal syndromes, where fragile sites associated with breakage and repair of chromosomal defects are transmitted through families. A high percentage of the inheritable and constitutive fragile sites have been mapped to genetic sites associated with human cancer.[51] These chromosomal rearrangements have been associated with malignancy in at least 6 out of the 16 inheritable fragile chromosome sites and have also been identified in other non-inherited fragile chromosome sites.[51] As a result of the chromosome fragility in these cases, deletions and chromosomal fragments may occur. Should the fragile sites break close to a proto-oncogene location, the activation of the oncogene may result in the malignant transformation of the cells. In several disorders in sexual differentiation, the incidence of gonadal tumors has been increased.

Familial associations with cancer

Although loss of a chromosome segment of a specific chromosome pair (heterozygosity) may be involved in the pathogenesis of certain tumors,[52,53] a specific chromosome from one of the parents appears to be given preference in particular situations.[54] Examples of this are the loss of a maternally derived gene on chromosome 11 in sporadic WT[55] and the successive loss of function of both alleles of RB (retinoblastoma susceptibility gene) in the development of retinoblastoma as well as certain sarcomas such as osteosarcoma.[54] Genetic processes other than chromosome anomalies may also be involved in the familial transmission of a tendency to develop certain tumors.

Large cohort studies of offspring of parents with cancer have failed to show an overall increased risk for tumors.[54] There is also little evidence to suggest that cancer treatment confers an additional risk. In a separate study of 36 survivors of 82 NNTs, the current authors found no familial increase in the incidence of malignancy, although chromosomal abnormalities were identified in three patients.[56] One patient had a chromosome 21 abnormality, one had trisomy 13, and in the other, a distinctive familial translocation pattern was located on the ninth chromosome in a girl with a neuroblastoma.[38] The lack of increase in incidence agrees with the findings of previous studies[12,39,40] where no inherited effects of childhood tumors or tumor therapy were identified in survivors of childhood neoplasms.

Other syndromes associated with an increased genetic risk of cancer

Although a family history may be observed in the group of neurocristopathies associated with neural crest abnormalities, the associated tumors appear outside the neonatal period. Examples of this are pheochromocytoma, von Recklinghausen's disease, Sturge–Wreber syndrome, tuberous sclerosis, and von Hippel–Lindau disease, as well as the MEN II tumor syndrome.

Other congenital syndromes that confer an increased risk of malignancy include the WAGR and Denys–Drash syndromes in WTs, the Beckwith–Wiedemann and Down syndromes, and neurofibromatosis (NF1 gene). There is an increased risk of leukemia and other tumors in patients with Down syndrome.[57] Leukemoid reactions may be more difficult to distinguish in the neonatal period.[58] Abnormalities of the neurofibromatosis 1 gene (NF1) have been identified in patients with von Recklinghausen's disease, and a number of different mutations on the tumor suppressor gene have been described in chromosome 17q. An additional NF2 suppressor gene has been identified on chromosome 22q, leading to tumors such as acoustic schwannomas and other neural tumors.

There is a certain amount of overlap in phenotypic expression in syndromes such as the Beckwith–Wiedemann, Denys–Drash, Simpson–Golabi–Behmel, and Perlman, as well as other overgrowth syndromes. Nephroblastomatosis may be a feature of a number of these syndromes, and long-term survey is required as these could put patients at risk for embryonic tumors.

There are additional associations between WT, aniridia, urogenital malformations and mental retardation (WAGR), and the Denys–Drash syndrome.[59] This latter syndrome

includes features of disorders of sexual differentiation, nephropathy, and WT. Although initially described only in males with pseudohermaphroditism,[59,60] this syndrome has been extended to include female children with ambiguous genitalia, nephropathy, and WT.[61] An observed constant association with genetic mutations located at chromosome 11p13 (WT1 or Wilms' tumor gene) and the Denys–Drash syndrome indicates a possible molecular marker for this syndrome. The exact site of the point mutation that was identified in the majority of cases was located on the WT1 exon 9, which affects the amino acid residue 394 arginine.[61] There is also an association between other tumors such as hepatoblastoma or adrenocortical carcinoma and WT, which may coexist in 6%–10% of patients.

Genetic factors that are involved in an increased risk of tumors include tyrosinosis, the MEN II and III syndromes, congenital adrenal hyperplasia, the basal cell nevus syndrome, and the Li–Fraumeni syndrome.[62] Genetic mutations predisposing to malignant disease include the Wilms' tumor 1 gene. In this instance, an 11p13 chromosomal defect is often typical. A further example is the neurofibromatosis type 1 gene, which is common in certain tumors. Gene amplifications have been reported in certain tumors. Amplified N-myc and N-ras oncogenes have been observed in neuroblastomas. This N-myc amplification has been shown to be associated with the more severe form of the malignancy.

Association with congenital malformations

Congenital malformations are inked to tumor formation [<1 year (OR = 16.8, 95% CI: 3.1–90) vs. >1 year of age]. There is also a fairly clear relationship to congenital abnormalities, which have been reported to occur inasmuch as 15% of NNTs. In one recent study, 15 out of 72 patients with a NNT had associated congenital abnormalities.[63] The role of genetic factors in development and the link between congenital malformation and tumors (e.g., neuroblastoma[64]) are also becoming clearer.

Possible increased susceptibility to environmental toxins

In addition to genetic factors, although limited in the neonatal period, environmental exposure is also a contender for promoting oncogenesis.

Although it is true that neonates have a limited exposure to environmental toxins having just been "born," environmental influences that affect the mother may also affect the unborn baby. These include environmental exposure to ionizing radiation, drugs taken during pregnancy, infections and tumors in the mother, and congenital malformations.

As a result, events occurring during pregnancy could be of key significance in the development of NNTs. Both the environmental and genetic factors may thus influence the development of a NNT in the offspring. It is therefore conceivable that both genetic and environmental factors may be operating (possibly in tandem) at this stage giving rise to a "unifying hypothesis" linking ontogeny to oncogenesis.

Environmental exposure may possibly influence vital signaling cascades during development. By way of example, these influences would, of necessity, have to occur during a period when normal developmentally specific mechanisms are influenced by multiple genetic and environmental factors in order to influence the epigenetic processes taking place during that period.[65] More recently, the importance of disturbances in epigenetic programming, which regulate both normal and neoplastic growth and development, are being further explored.[66,67]

The fact that NNTs have been protected from extensive environmental influences tends to mitigate against this being a major role player in their pathogenesis. However, environmental influences on epigenetic factors have already been demonstrated in patients exposed to environmental toxins in some adult tumors.[68]

It stands to reason, therefore, that a study of those genetic and environmental factors with the potential to influence this process has the potential to provide considerable information about both cancer etiology as well as the natural history of tumors, including their development and progression.

The resulting molecular epidemiological approach in investigating childhood tumors is enhanced by the current available technology, which may permit the characterization of connections between exposure and subsequent health effects in newborns by means of biomarkers (e.g., mutations in cord blood DNA).[69]

Radiation-induced tumorigenesis

One example of environmental influences is that of ionizing radiation, which has been clearly implicated in the etiology of a number of tumors in children. This may involve prenatal as well as postnatal exposure. There is a dose-related increase in tumor incidence or a tendency for tumors to occur at a younger age following prenatal or neonatal radiation exposure.[70] This is also true of internally deposited radionucleotides administered in the prenatal or neonatal periods.[71]

It is clear from experimental evidence that deletions, point mutations, translocations, and other genetic abnormalities occur as a result of ionizing radiation. As a result, a state genomic instability may occur, which may, in turn, result in malignant transformation. There does appear to be an increased susceptibility to ionizing radiation in the Li–Fraumeni syndrome mouse model (p53-deficient mice), which suggests some environmental influence in the development of tumors.[72]

Effect of drugs in pregnancy

It is becoming clearer that fetal exposure to endocrine disruptors and hormonally active substances (e.g., diethylstilboestrol) affects the prevalence of reproductive

abnormalities and metabolic disorders, and thus influences cancer.[73]

Drugs may act as carcinogens or cocarcinogens in association with other agents or a particular genetic background. There is also clear evidence that tumors may arise in the children of mothers taking medication. One of the best examples of this is the fetal hydantoin syndrome.[74] There is some evidence of tumors arising from estrogens taken during pregnancy, and sacrococcygeal tumors have also been associated with maternal intake of acetazolamide.[75] This may be a greater problem than was initially thought. Satgé et al.[76] showed a history of medications being taken in 39 out of 89 (44%) neonatal tumor patients. Out of the 39 tumors, 9 were malignant, of which the main types were neuroblastomas and teratomas. Three groups of drugs were identified: IARC group 1, diethylstilboestrol and oral contraceptives; IARC group 2, possibly carcinogenic to humans; and IARC group 3, where no association has been proven. To date, the association of vitamin K with carcinogenesis remains uncertain.[77]

Environmental exposure

Results of epidemiological studies are inconsistent as far as environmental exposure is concerned, but only weak associations with risk factors such as smoking have been identified.[78] Other environmental factors such as exposure to electromagnetic radiation have proved to be difficult to determine from an epidemiological point of view.

SPECIFIC CLINICAL ASSOCIATIONS OF NNTs

Retinoblastoma

Much of the understood relationship between genetics and tumors of childhood really lies in the seminal work of Knudson[47] who in 1971 developed his "two-hit theory" of oncogenesis in retinoblastoma based on an analysis of the age of presentation of hereditary as opposed to the nonhereditary cases. His hypothesis that these tumors resulted from two separate genetic events was extended to suggest that these events could be mutations of the same RB1 gene. It has subsequently been shown that 90% of individuals with the RB1 gene mutation will develop a retinal tumor. A small number of these patients (5%) have additional associated genetic disturbances (e.g., deletions or translocations at 13q14).

To date, deregulated expression in more than 260 genes have been associated with retinoblastoma. An understanding of the function of these genes not only provides valuable insights into oncogenesis in retinoblastoma but also has yielded possible therapeutic target sites (e.g., MCM7 and WIF1) currently under investigation.[79]

Retinoblastoma remains the commonest intraocular tumor of childhood, with the average age of diagnosis being at 11–12 months of age for bilateral disease and 23 months for unilateral tumors. In cases with a strong family history and a high index of suspicion, diagnosis may be made in the perinatal period.

The retinoblastoma protein (pRB) is part of the control of genes involved in the cell cycle and, as such, interacts with a number of transcriptional factors by modulating their activity. Therefore, deregulations and/or mutations of the retinoblastoma protein (RB/RB1) pathway have been observed in many human cancers, suggesting a fundamental role in oncogenesis. Patients with RB1 mutations carry a risk of developing other tumors such as osteogenic sarcomas, fibrosarcoma, melanoma, and even breast carcinoma in early adult life.

Neuroblastoma

Neuroblastoma is one of the most commonly occurring malignant solid tumors in childhood, which is often being advanced at diagnosis, commonly metastasizing widely to bone marrow, bone cortex, liver, lymph nodes, and lung. The tumor arises from the neural crest origin and can originate from any site along the distribution of the sympathetic chain. More than 90% are active in secreting biochemical substances, which helps in diagnosis as catecholamine metabolites may be measured in the urine.

Genetic factors play a major role in development and the link between maldevelopment and tumors. A positive association between congenital malformation and neuroblastoma has been reported in at least one recent study [odds ratio (OR) = 2.2, 95% confidence interval (95% CI): 1.1–4.5],[64] being particularly linked to those tumors presenting at <1 year of age (OR = 16.8, 95% CI: 3.1–90) as opposed to those presenting at >1 year of age.

Neuroblastoma itself may demonstrate a unique clinical behavior within the perinatal period. Although spontaneous regression is known to occur in neonates, it does not appear to be limited to fetal period or stage IVS neuroblastoma (small primary tumour, liver, skin and/or bone marrow metastases). It is noteworthy that aggressive neuroblastoma tumors are characterized by increased expression of cell cycle genes, whereas more mature forms like ganglioneuroma and ganglioneuroblastoma that mostly express genes related with neural development are associated with a more benign course.

It is also noteworthy that a few of the perinatal neuroblastoma tumors have n-myc amplification. Although its action is uncertain, other oncogenic genes alter other genes like beta-catenin, which leads to excessive cell growth (e.g., Activin-A by MYCN).

Certain tumors, although malignant in appearance, may undergo spontaneous regression, whereas others metastasize widely and aggressively. Studies have shown a favorable outcome for neuroblastoma in the majority of mass screened perinatal patients,[19,80] suggesting either a better biological profile or operative developmental signaling pathways, which still function in the perinatal period. In addition, stage IVS neuroblastomas, although widely spread [including a massively enlarged liver and extensive subcutaneous (blueberry muffin) lesions], have a relatively good clinical prognosis.

Neuroblastoma tumor cells are associated with molecular genetic features in up to 80% of cases, many of which are of biological and clinical significance as prognostic factors and are currently of value in directing treatment.

The most important of these are MYCN amplification, deletion of chromosome 1p, ploidy, additional copies of chromosome 17q, and the expression of the gene for the neurotrophin nerve growth factor gene TRKA. Multiple areas of LOH and copy number gain were seen. In many cases, the defect is found to be on chromosomes 1, 11, and 17. Gain of copy number on 17q has recently been reported in 95% of cases studied,[81] with one of the most consistent changes being a deletion on the short arm of chromosome 1 (1p36.1–1p36.3). Whereas 1p LOH is encountered in one-third of cases,[82] inactivation of the tumor suppressor gene at 11q23.3 has been found to be an even more frequently encountered element of malignant progression being identified in up to 68%.[83] LOH on both chromosomes 11q and 1p was mostly accompanied by copy number loss, indicating homozygous deletion. It is also highly associated with occurrence of chromosome 3p LOH.

Additional chromosomal abnormalities have been identified at 4p, 6q, 9q, 10q, 12q, 13q, 14q, 16q, 22p, and 22q.[84] Amplification of the n-Myc oncogene (usually found on chromosome 2) has been associated with a more advanced form of the malignancy and is a poor prognostic sign.[85] Few of the perinatal neuroblastomas have n-myc amplification, although 10%–20% have unfavorable histological features. Recent research into high-risk neuroblastoma without MYCN amplification has shown that other oncogenic genes may deregulate MYC via altered beta-catenin signaling (a transcriptional target of beta catenin), indicating some degree of interdependence with other signaling pathways.[86] Recent reports of the downregulation of Activin-A by MYCN offer an explanation for this as deprived neuroblastoma cells experience a decrease in growth-inhibitory signal transduction leading to excessive cell growth.[87] In addition, the expression of TrkA has recently been shown to inhibit angiogenesis and tumor growth in neuroblastomas, suggesting possible new treatment options.[88] It is also interesting to note that p53 gene mutations are absent in neuroblastomas,[89] although present in other tumors of childhood.

In addition, molecular genetic features have been reported in >80% neuroblastoma cases. This is particularly true of high-risk patients, in whom a number of genetic alterations exist. Examples of these include MYCN on chromosome 2, which is a poor prognostic sign. Additional high-risk sites include 1pLOH, unbalanced 11q, as well as gains of Chr 17 and 7. It has been shown that expression of neurotrophin nerve growth factor gene TRKA inhibits angiogenesis and tumor growth in neuroblastoma. Other oncogenic genes (e.g., Activin-A by MYCN) alter beta-catenin signaling, which leads to excessive cell growth.

Few perinatal neuroblastoma have n-myc amplification and have a chance to regress. This spontaneous regression, which occurs in the neonate, is not, however, limited to fetal period or stage IVS. Aggressive neuroblastoma tumors are characterized by an increased expression of cell cycle genes. On the other hand, the more mature ganglioneuroma and ganglioneuroblastoma subtypes express genes associated with neural development.

Genomic studies of neuroblastomas have brought to light a number of possible biological mechanisms to explain the phenomenon of spontaneous regression in certain cases. Among others, these include neurotrophin deprivation, humoral or cellular immunity, loss of telomerase activity, and alterations in epigenetic regulation.[90]

TERATOMA

Germ cell tumors account for approximately 3% of pediatric malignancies worldwide and occur in gonadal (male and female) and extragonadal sites. Epidemiology should include abortions and stillbirths as the related mortality rate is high. The majority of teratomas are located in the sacrococcygeal region and gonads in childhood. Sacrococcygeal tumors are mostly benign at birth, and the majority do not develop to malignancy if adequate surgical removal is carried out before the infant is 3 months of age. After this time, the risk of malignancy increases if residual tumor is present, and older children may require chemotherapy along with delayed surgical excision.

Teratomas are thought to arise from the primordial germ cells as a result of an early event. A genetic tendency toward spontaneous gonadal teratomas is seen in a specific strain of experimental mice (strain 129).[91] An association with autosomal dominant familial recurrence has been reported, and there also appears to be a Mendelian dominant genetic predisposition to the development of a presacral mass in association with anorectal, sacral, and urogenital abnormalities.[92] Patients with an imperforate anus and a hemisacrum have a high incidence of presacral masses, which are teratomas and may occasionally be malignant.[92] Recent evidence points to an association with the long arm of chromosome 7 and Currarino's triad.[93] Mediastinal teratomas have been shown to develop in the second trimester.[94] Their sensitivity to chemotherapy and the existence of reliable tumor markers are important prognostic factors.

SOFT TISSUE TUMORS

STS are not uncommon in childhood and whereas the majority are benign lesions of connective tissue, a number of extremely aggressive tumors exist. There are arguably three separate clinical groups of STS encountered in childhood (viz., CFS, RMS, and non-rhabdomyosarcoma).[95]

Spicer[96] classified congenital fibrosarcoma separately to differentiate it from the more aggressive type of fibrosarcomas with similar histopathologic features seen in adults as they mostly have a favorable outcome and metastasize rarely. Classifying STS on prognosis and outcome, he considered that tumors of intermediate prognosis included RMS, peripheral neuroectodermal tumors (PNET), undifferentiated sarcomas, and malignant melanomas, whereas tumors with a uniformly bad prognosis included Kaposi

sarcoma, malignant schwannoma, triton tumors, and juvenile hyaline fibromatosis, as well as visceral fibromatosis.

Rhabdomyosarcoma

RMS accounts for 10% of neonatal malignancies,[97] being the most common malignant STS even in the perinatal period.[21] It has a number of genetic associations that differentiate the histological subtypes and is associated with a number of genetic syndromes [viz., Beckwith–Weideman, Li–Fraumeni, and WAGR syndromes and neurofibromatosis (Type 1)]. This suggests a genetic basis for its early appearance in the neonatal period.

Associated genetic variations include loss of heterogeneity of the short arm of chromosome 11 (11p15 locus 12) in embryonal tumors, which leads to an overexpression of the insulin growth factor II (IGFII) gene. Equally, a subset of alveolar RMS has a unique chromosomal translocation between chromosomes 2 and 13, viz. (t[2;13) (q35;q14)).[98,99] This is close to the junction of the PAX3 gene, which controls neuromuscular development,[100] and the PAX/FKHR fusion gene is found in as many as 60% of alveolar RMS. A further 10% of patients with particularly poor prognosis may also carry the Ewing's sarcoma [EWS/ETS fusion genes (occasionally along with the PAX/FKHR gene)].

Numerous other genetic variations have been reported including frequent gains of chromosomes 2, 7, 8, 11, 12, 13q21, and 20, as well as losses of 1p35–36.3, 6, 9q22, 14q21–32, and 17.[101] A further loss of 1p36[102] corresponds to the locus for the paired home box PAX 7, which is characteristically altered in alveolar RMS tumors. The 1p region is interesting as it is also associated with neuroblastomas. Additional associations between mutations in the p53 tumor suppressor gene are also associated with adverse outcome.

STS and the Beckwith–Wiedemann syndrome

The Beckwith–Weideman syndrome (BWS; macrosomia, macroglossia, omphalocele, and hemihypertrophy) is associated with genetic and/or epigenetic alterations that modify imprinted gene expression on chromosome 11p15.5. There is an increased risk of soft tissue sarcomas (approx. 7.5%) especially if hemihypertrophy is present. Oncogenesis is associated with the detection of abnormal myogenic transcription factors (MyoD, Myogenin, and Myf5) and the PAX/FHKR chimeric transcription factors. Detection of other fusion genes such as EWS/WT1 in desmoplastic small round cell tumors, EWS/ATF in clear cell sarcoma, SSX/SYT in synovial cell sarcoma, or the TLS/CHOP in liposarcoma has also been described. An overexpression of MyoD in RMS is thought to inhibit the development of muscle cells and characteristically marks these tumors.[103]

The increased tumor risk in the Beckwith–Weideman overgrowth syndromes and the associated WT, hepatoblastoma, and hemihypertrophy are probably due to the complex genetic/epigenetic abnormalities of the imprinted 11p15 region.[104,105] A specific cancer risk is associated with specific areas of the gene[106] with the most common constitutional abnormalities currently appearing to be epigenetic, with aberrant methylation occurring at H19 or LIT1. As a result, untranslated RNAs are recorded on the gene at 11p15. Variations in H19DNA methylation were found to be significantly increased in at least one report [viz., 56% (9/16) vs. 17% (13/76; $p = .002$)], but not LIT1 alterations.

Ewing's family tumors

Although the cell of origin of Ewing's sarcoma is unknown, the Ewing's family of tumors most frequently has a specific translocation that results in expression of the EWS/FLI1 fusion protein responsible for malignant transformation.[107] Although a number of EWS/FLI1 downstream targets have been identified, the exact details of the oncogenic mechanism remain uncertain. It is currently thought that the FLI, ERG, FEV, ETV1, and ETV4 genes appear to be involved in chimera formation, which all upregulate EAT-2 (a previously described EWS/FLI1 target). EWS/FLI1 dysfunction appears to then result in functional activation of the retinoblastoma (pRB) family proteins, which are key mediators of the resulting probable oncogenic transformation.[108]

HEPATOBLASTOMA

Hepatoblastoma is the most common malignant liver tumor and embryonal tumor occurring particularly in the younger child and has also been associated with a low birth weight in the neonate.[109]

Although up to one-third of hepatoblastomas are associated with congenital abnormalities, the majority of cases are sporadic and the molecular pathogenesis poorly understood. Familial recurrence is extremely rare with the exception of families with adenomatous polyposis coli (FAP).[110] As a result, it is becoming clear that FAP-APC gene mutations result in transcription–activation and oncogenesis in these cases.

There is also considerable support for associations with trisomies 2, 8, and 20 in the development of HB.[111] In addition, gains on chromosomes 1q+ 2 (2q24) and 8q and 20 appear to be associated with a poor outcome. Known associations with the BWS and hemihypertrophy suggest a common genetic pathway (viz., LOH at the 11p15 site, which contains an insulin-like growth factor II and the H19 gene).

Congenital hepatoblastoma appears to have a poorer prognosis than those occurring in the older child with metastatic lesions being reported at unusual sites (viz., brain,[112] iris and choroid,[113] and placenta[114]). The latter may indicate tumor seeding during pregnancy via the fetal circulation.

An emerging association is with the CTNNB1 (beta-catenin) gene association with HB, particularly the embryonal subtype. The incidence of mutation of this gene in HB has been reported to vary widely in HB (13%–70%). Nevertheless, the SIOPEL study in 2011 found an 87% (85/98) aberrant β-catenin expression in HB specimens. Met-activated β-catenin was found in 79% of cases.[115]

WILMS' TUMOR

WT is the most common pediatric renal tumor with a peak age of incidence of 3–4 years. Although rare in the neonatal period, patients with synchronous bilateral WT, familial cases, and those with abnormalities are noted to be significantly younger. Predisposing associations with aniridia, congenital abnormalities of the genitourinary tract, and hemihypertrophy may be associated with nephroblastomatosis, which may lead to an early WT (Table 84.5). The familial associations have been shown to be part of an autosomal dominant trait and are of the order of 1% with a somewhat slight female preponderance, particularly in multicentric and bilateral tumors.

The genetic factors involved in WT are much more complex than those involved in other tumors such as retinoblastoma. Many of the genes implicated in Wilms' tumorigenesis are involved in the control of nephron progenitors or the microRNA (miRNA) processing pathway. Current research suggests important roles for miRNAs in WT etiology.[116] The familial associations have been shown to be part of an autosomal dominant trait and are of the order of 1% with a somewhat slight female preponderance, particularly in multicentric and bilateral tumors.

WT have been associated with at least two genetic variations (viz., 11p13; 11p15). Associations between WT and aniridia, urogenital malformations, and mental retardation (WAGR) and the Denys–Drash syndromes[60,61] led to the identification of a constitutional chromosomal deletion in the short arm of one copy of chromosome 11 p13 (the WT1 gene).

Table 84.5 Syndromes associated with WT

1. Aniridia (0.75%–1%)
2. Hemihypertrophy (3.3%)
3. BWS (3.7%)
4. Musculoskeletal abnormalities (2.9%)
5. Genitourinary abnormalities (5.2%)
6. Other syndromes associated with WTs
Denys–Drash syndrome
Nephroblastoma
Male pseudohermaphroditism
Glomerulonephritis
Nephrotic syndrome
Renal failure
WAGR syndrome (11p13 deletion)
Nephroblastoma
Anorectal malformation
Genitourinary anomalies
Mental retardation
BWS
Klippel–Trelaunay syndrome
Other associated tumors
Hepatoblastoma (6%–10% of WTs)
Adrenocortical carcinoma

The Knudson model for WT has been validated through molecular identification of WT1 gene variation.[117,118] The WT1 gene encodes a transcription factor that appears to act both as a tumor suppressor gene[119] as well as an important regulator of renal embryological development. The deletion of this gene results in the development of a WT[120] by encoding a zinc finger transcription factor, which binds GC-rich sequences and acts as either an activator or repressor of transcription for a number of growth factors (including Igf-2)[121]. This may be a possible explanation of the mechanism of action of WT1 in the pathogenesis of WT.

The WT1 gene variations are only present in approximately 20% of WTs, suggesting further genetic associations. Despite some overlap with the WT1 gene, a combination of different genes could account for up to one-third of WTs.[122]

In addition to the WT1 gene at 11p13, there is evidence of a second WT gene at 11p15 (WT2 gene), which is associated with the BWS.

In addition, a reported high frequency of loss of heterozygosity (LOH) at 1p35–p36 (DIS247) suggests involvement in the pathogenesis of WT.[123] Further, genes (e.g., WT3 and WT4) also appear to be implicated in the oncogenesis of WTs as are gains of 1q and deletions of chromosome 22 associated with worst prognosis of WTs.

More recently, the WTX gene [Xq11.1] has been reported to be mutated in WTs. It is of interest that the 11p15 variation and the WTX genes appear to occur with similar regularity in these tumors.

Further, genetic pathways have also been reported. An association between the WNT/beta-catenin signaling pathway (the CTNNB1 gene, encoding beta-catenin) is also known.[124,125] This suggests that Wnt signaling pathway dysregulation also plays an oncogenic role in certain WTs. Further, genomic gain of the proto-oncogene transcription factor gene MYCN is associated with anaplasia and a decreased relapse-free and overall survival, independent of the histologic findings.[126] In addition, a LOH for 16q is a structural alteration identified in 20%–30% of WTs, and p53 alteration also appears to be required for the progression to the anaplastic subtype. Further, associations with p53 analogues (p73 and p63/KET) suggest that association with the p53 family may be important to cell growth and differentiation.[127] Haploinsufficiency in the PAX6 gene is also strongly associated with aniridia and may be involved.[128]

Familial WT does not, however, map to the 11th chromosome, as the known gene FWT1 is on 17q12–q21 and FWT2 on 19q13. Other susceptibility genes still remain to be identified.

OTHER TUMORS

Other genetic aberrations associated with tumors, such as the loss of heterozygosity on chromosome 5q, in identifying the gene for familial polyposis of the colon, defects in tumor-suppressive genes on 17q (p53) and 18q (DCC) in carcinoma of the colon, and translocation of the end of the long arm of chromosome 8 with chromosome 14, or an

alteration in C-myc regulation or p53[129] in Burkitt's lymphoma, are interesting associations with pediatric tumors, but are not particularly associated with the neonatal period.

ANTENATALLY DIAGNOSED TUMORS

Clinical approach to antenatally diagnosed tumors

The reasons for highlighting NNTs are manifold but include the following:

1. Increased diagnosis of NNTs due to routine ultrasonography during pregnancy brings to light tumors whose natural history and optimal management are unclear.
2. Increased knowledge and understanding of pathophysiology and biological behavior of tumors may reduce unnecessary harmful forms of therapy.
3. Molecular genetics in these tumors identifies risk factors and provides models for understanding carcinogenesis in other tumors.
4. Environmental and teratogenic factors may be identified.

All evidence points toward the fact that the natural history of NNTs is different (mostly better) than that of comparable tumors in older children. The basis of this behavior is largely unknown, and hard epidemiological and etiological data in this group are lacking.

It is important that the identification of the genetic associations of these tumors continues and the cancer-producing genes to identify the genetic alleles associated with malignancy are investigated further. In addition, it is important that families with a genetic susceptibility to malignant tumors be investigated in order to identify specific genetic loci, which may or may not be related to a specific allele. Because of the rarity of these tumors, it is clear that international collaborative studies and research projects are necessary to achieve this goal.

THERAPEUTIC CONSIDERATIONS

There is also a paucity of objective information on the optimal treatment and long-term outcome of NNTs[12] and the impact of therapeutic measures to take into consideration.[13,130–132]

Hemangiomas and vascular malformations

BELINDA HSI DICKIE, ARIN K. GREENE, AND STEVEN J. FISHMAN

INTRODUCTION

Vascular anomalies are disorders of the endothelium that usually present during childhood. These lesions affect all parts of the vasculature: capillaries, veins, arteries, or lymphatics. Although nearly always benign, vascular anomalies may involve any location. In addition to disfigurement, local complications include obstruction, bleeding, infection, and pain. Systemic sequelae can include thrombocytopenia, pulmonary embolism, congestive heart failure, sepsis, and even death.

A biologic classification of vascular anomalies has clarified the difference between vascular anomalies based on physical findings, natural history, and cellular characteristics.[1] This classification has been expanded and adopted by the International Society for the Study of Vascular Anomalies (ISSVA).[2] Vascular anomalies are broadly divided into two groups: tumors and malformations (Table 85.1). Vascular tumors are characterized by endothelial cell proliferation (Figure 85.1). Vascular malformations, in contrast, arise from dysmorphogenesis and have normal endothelial cell turnover (Figure 85.2).

VASCULAR TUMORS

Infantile hemangioma (IH)

CLINICAL FEATURES

IH is a benign tumor of the endothelium that affects approximately 4%–5% of Caucasian infants.[1–4] It is more frequent in premature children and females (3:1 to 5:1).[5] IH typically is single (80%) and involves the head and neck (60%), trunk (25%), or extremity (15%).[3] The median age of appearance is 2 weeks, although 30%–50% of lesions are noted at birth as a telangiectatic stain or ecchymotic area.[6] IH grows faster than the rate of the child during the first 9 months of age (*proliferating phase*).[7] When IH involves the superficial dermis, it appears red. A deep hemangioma or lesion that does not have cutaneous involvement may not be appreciated initially, but the child may present at 3–4 months of age when it is large enough to cause a visible deformity. The overlying skin may have a bluish discoloration. By 9–12 months of age, the growth of IH plateaus to approximate that of the infant.[7] After 12 months of age, the tumor begins to shrink (*involuting phase*); the color fades and the lesion flattens. Involution stops in approximately 50% of children by 5 years of age (*involuted phase*).[6] After involution, one-half of children will have an abnormality: residual telangiectasias, scarring, fibrofatty residuum, redundant skin, or destroyed anatomical structures.

DIAGNOSIS

Ninety percent of IH is diagnosed by history and physical examination. If the history is unclear, confirmation of diagnosis can be made with Doppler ultrasound. IH appears as a soft-tissue mass with fast-flow, decreased arterial resistance, and increased venous drainage.[8] Further imaging is not usually required, but is obtained in complicated, internal IH, or part of a workup for associated syndromes. On MRI, IH is isointense on T1, is hyperintense on T2, and enhances during the proliferating phase.[9] Involuting IH has increased lobularity and adipose tissue; the number of vessels and flow is reduced.[9] Rarely, biopsy is indicated if malignancy is suspected or if the diagnosis remains unclear following imaging studies. Immunohistochemistry for GLUT1 (erythrocyte-type glucose transporter 1) is specifically expressed in proliferating IH and immunostaining and can differentiate IH from other lesions.[10]

CLINICAL CONSIDERATIONS

Head and neck memangiomas

Ten percent of proliferating IH cause significant deformity or complications, usually when located on the head or neck.[11] Ulcerated lesions may destroy the eyelid, ear, nose, or lip. IH of the scalp or eyebrow can result in alopecia.

Table 85.1 Biological classification of vascular anomalies

	Malformations	
Tumors	**Slow flow**	**Fast flow**
Infantile hemangioma (IH)	Capillary (CM)	Arteriovenous (AVM)
Congenital hemangioma (CH)	Venous (VM)	
Kaposiform hemangioendothelioma (KHE)	Lymphatic (LM)	
Pyogenic granuloma (PG)		

Periorbital hemangioma can block the visual axis or distort the cornea causing amblyopia. Subglottic hemangioma may obstruct the airway; tracheostomy rarely may be necessary. IH of the periorbital region, ear, and nose are treated more aggressively to prevent complications from mass effect or ulceration.

Multiple hemangiomas

Although 20% of infants will have more than one IH, occasionally a child will have five or more small (<5 mm), dome-like lesions termed *hemangiomatosis*.[6] These children are at increased risk for IH of internal organs. The liver is most commonly affected; the brain, gut, or lung are rarely involved. Ultrasonography (US) should be considered to rule out hepatic IH in patients with greater than five cutaneous hemangiomas, hepatomegaly, or any signs of shunting on physical examination.

Hepatic hemangiomas

The liver is the most common extracutaneous site for IH, which may be focal, multifocal, or diffuse (Figure 85.3).[12] Although most hepatic IH are nonproblematic and discovered incidentally, some tumors can cause heart failure, hepatomegaly, anemia, or hypothyroidism. Ninety percent of fast-flow hepatic lesions are hemangioma; arteriovenous malformation (AVM), hepatoblastoma, and metastatic neuroblastoma are less common and do not demonstrate significant shunting on imaging.[12] Focal hepatic IH usually are asymptomatic unless they have associated direct macrovascular shunts (hepatic artery to hepatic vein and/or portal to hepatic vein). These direct shunts can lead to high-output cardiac failure. Focal hepatic lesions are not associated with cutaneous lesions. They are not typical IH, but rather the hepatic presentation of rapidly involuting congenital hemangioma (RICH).[13] Multifocal hepatic IH are typical IH, immunopositive for GLUT1, and may be associated with cutaneous lesions. Although usually asymptomatic, multifocal lesions also can have associated macrovascular shunts that can cause high-output cardiac failure. In either focal or multifocal variants, shunts may resolve with tumor involution, which in the multifocal type may be hastened pharmacologically. Embolization of the shunts, although technically demanding, will quickly control cardiac failure.[14] Diffuse hepatic IH can cause massive hepatomegaly, respiratory compromise, or abdominal compartment syndrome. Infants also are at risk for hypothyroidism and subsequent irreversible brain injury because the tumor expresses a deiodinase, which inactivates thyroid hormone.[15] Patients require thyroid stimulating hormone monitoring and, if abnormal, thyroid replacement, often in massive doses, until the IH undergoes involution.

Lumbosacral hemangioma

Large, superficial, plaque-like, or reticular IH rarely may be associated with underlying spinal, urogenital, or anorectal malformations when it is located in the lumbosacral midline (tethered spinal cord, anorectal and genital malformations, renal anomalies, lipomyelomeningocele).[16,17] US is obtained to rule out associated spinal anomalies in infants less than 4 months of age. MRI is indicated in older infants or when US is equivocal. This constellation of anomalies is known as the PELVIS or SACRAL syndrome.[17,18]

PHACES association

PHACES association affects 2.3% of patients with IH and consists of a plaque-like IH in a "segmental" or trigeminal dermatomal distribution of the face with at least one of the following anomalies: posterior fossa brain malformation, hemangioma, arterial cerebrovascular anomalies, coarctation of the aorta and cardiac defects, eye/endocrine abnormalities, and sternal clefting or supraumbilical raphe.[19] Ninety percent of infants are female, and cerebrovascular anomalies are the most common associated finding (72%).[20] Because 8% of children with PHACES have a stroke in infancy, patients should have an MRI to evaluate the brain and cerebrovasculature.[21] Infants are referred for ophthalmologic, endocrine, and cardiac evaluation to rule out associated anomalies.[21]

NON-OPERATIVE MANAGEMENT

Most IH are managed by observation because 90% are small, are localized, and do not involve aesthetically or functionally important areas. During the proliferative phase, 16% of lesions will ulcerate; the lips, neck, and anogenital region are the most common areas to break down.[22] Other complications include bleeding and infection.[22] To reduce the risk of ulceration, the IH is kept moist during the proliferative phase with hydrated petroleum to minimize desiccation as well as to protect against incidental trauma. Using a petroleum gauze barrier or silicone pad dressing may further protect IH. If ulceration develops, it is managed with local wound care.

Beta-blockers

Until recently, the mainstay of treatment for IH was corticosteroids. However, in 2008, Labreze et al.[23] reported on improvement of hemangiomas in 11 patients after treatment

Figure 85.1 Vascular tumors of childhood. **(a)** Infantile hemangioma (IH) in a 3-month-old female. The lesion was noted 2 weeks after birth and subsequently enlarged. It was treated with corticosteroid injection. **(b)** Rapidly involuting congenital hemangioma (RICH) in a 3-week-old male. The lesion was fully grown at birth and rapidly involuted over the first year of life. **(c)** Non-involuting congenital hemangioma (NICH) in a 2.5-year-old male; the vascular mass had not changed since birth. **(d)** Pyogenic granuloma in an 8-year-old female with a 3-month history of a bleeding lesion. **(e)** Kaposiform hemangioendothelioma (KHE) in a 5-week-old neonate treated with vincristine.

Figure 85.2 Vascular malformations of childhood. **(a)** Capillary malformation (CM) of the scalp of a 2-month-old female. **(b)** 7-month-old female with a macrocystic lymphatic malformation (LM) of the right face treated with sclerotherapy. **(c)** 7-year-old female with a diffuse venous malformation (VM) of the right lower extremity managed with compression stockings. **(d)** 16-year-old male with an arteriovenous malformation (AVM). **(e)** 1-year-old female with a combined capillary–lymphatic–venous malformation (CLVM) of the right lower extremity with overgrowth (Klippel–Trenaunay syndrome).

with propranolol. Since that time, there have been multiple published reports on the efficacy of β-blockers on the treatment of IH.[24]

Although the exact mechanism of action of β-blocker is not established, it is hypothesized that it works on vasoconstriction of the vessel, inhibition of angiogenesis, and induction of apoptosis. β-Adrenergic receptors are expressed on the IH endothelial cells, especially in proliferation.[25–28]

Systemic beta-blockers

Oral beta-blockers are usually started at a low dose and escalated. The most commonly used β-blocker is propranolol, and treatment dose is 2–3 mg/kg/day divided into two or three times a day dosing. On more complicated lesions, or diffuse or multifocal liver lesions, the dose is increased to 3 mg/kg/day. In our institution, baseline ECG is obtained and if clinically indicated, an ECHO is also done, prior to

initiation of β-blockers. Infants younger than 1 month of age are monitored as inpatients on telemetry during escalation of dosage, whereas older infants are started in the outpatient setting. Heart rate, blood pressure, and blood glucose levels are monitored for 3–4 hours after the oral dose. Effect on the IH can be seen within days of initiation of the propranolol. Duration of therapy is usually determined by the response of the IH. To prevent any rebound growth, propranolol is continued until the IH is in the involutional phase.

Side effects of the β-blockers are minimal, but there are reports of hypoglycemia, diarrhea, and increased reflux.

Topical beta-blockers

For superficial hemangiomas, topical application of beta blockers can be used two to three times a day. Although there is some systemic absorption, it is not as effective on deep hemangiomas. Topical beta-blockers may result in lightening of the lesion and prevent further growth of the IH.[29]

Corticosteroids

Previously the first line of medical management of IH, corticosteroids, are now used less frequently due to the side effects. On complicated airway, periorbital, diffuse liver lesions, systemic steroids may be used in conjunction with β-blockers.

Systemic corticosteroid

Corticosteroid has been used to treat IH for over 40 years and has proven to be very safe and effective.[30–33] Overall, 84% of patients treated with different doses of corticosteroid will have (1) stabilization of growth or (2) accelerated regression.[32] Almost all patients, however, will respond to 3 mg/kg/day.[32]

Complications of systemic corticosteroid for the management of IH have been studied, and no adverse effects on neurodevelopment have been found.[33] Short-term morbidity includes cushingoid face (71%), personality change (29%), gastric irritation (21%), fungal (oral or perineal) infection (6%), myopathy (1%), decreased gain in height (35%), and decreased gain in weight (43%).[31] These findings resolve after the completion of therapy. Long-term complications of corticosteroid such as aseptic necrosis of the femoral head, diabetes, osteoporosis, long-term adrenal insufficiency, cataracts, and glaucoma have not been noted in patients treated with corticosteroid for IH.[31,34,35]

Topical corticosteroid

Topical corticosteroid has minimal efficacy, especially against IH involving the deep dermis and subcutis. Ultrapotent agents may be effective for small, superficial IH; however, their efficacy is inferior to intralesional corticosteroid. Although lightening may occur, if an underlying mass is present, it likely will not be affected.[36] Adverse effects include hypopigmentation, skin atrophy, and possible adrenal suppression.

Intralesional corticosteroid

Small, well-localized IHs that obstruct the visual axis or nasal airway, or those at risk for damaging aesthetically sensitive structures (i.e., eyelid, lip, nose), are best managed

by intralesional corticosteroid. Triamcinolone (3 mg/kg) stabilizes the growth of the lesion in at least 95% of patients, and 75% of tumors will decrease in size.[37] The corticosteroid lasts 4–6 weeks, and thus, infants may require additional injections during the proliferative phase. Intralesional corticosteroid may cause subcutaneous fat atrophy. Blindness has been reported following injection of periorbital hemangioma, possibly due to embolic occlusion of the retinal artery.[38,39]

Embolic therapy

High-output congestive heart failure may be caused by macrovascular shunts seen with focal or multifocal hepatic lesions, or very rarely large nonhepatic IH. Embolization may be indicated for the initial control of heart failure, while the therapeutic effects of systemic corticosteroid are pending. Cardiac failure can recur even after initial improvement, and continued drug therapy after embolization may be indicated until the child is approximately 12 months of age when natural involution begins.

Laser therapy

Pulsed-dye laser treatment for proliferating IH is contraindicated. The laser penetrates only 0.75–1.2 mm into the dermis and thus only affects the superficial portion of the IH. Although lightening may occur, the mass of IH is not affected and accelerated involution does not occur.[40,41] Instead, patients have an increased risk of skin atrophy and hypopigmentation.[41] The thermal injury delivered by the laser to the ischemic dermis increases the risk of ulceration, pain, bleeding, and scarring.[42] The pulsed-dye laser is indicated, however, during the involuted phase to treat residual telangiectasias. Destructive laser therapy may be useful in airway hemangioma to avoid tracheostomy while awaiting successful response to pharmacotherapy.

OPERATIVE MANAGEMENT

Proliferative phase (infancy)

Operative treatment in infancy generally is not recommended. The tumor is highly vascular during this period, and the patient is at risk for blood loss, iatrogenic injury, and an inferior aesthetic outcome, compared to excising residual tissue after the tumor has regressed. Factors that lower the threshold for resection of a problematic proliferating IH include the following: (1) failure or contraindication to corticosteroid, (2) well localized in an anatomically safe area, (3) complicated reconstruction is not required, and (4) resection will be necessary in the future and the scar will be the same. Circular lesions located in visible areas, particularly the face, are best treated by circular excision and purse-string closure.[43] This technique minimizes the length of the scar as well as distortion of surrounding structures. A lenticular excision of a circular hemangioma will result in a scar as long as three times the diameter of the lesion, while a two-stage circular resection followed by lenticular excision 6–12 months later will leave a scar of approximately the same length as the diameter of the original hemangioma.[43]

Involuting phase (early childhood)

While operative management of IH generally is avoided during the proliferative phase, resection during involution is much safer because the lesion is less vascular and smaller. Because the extent of the excision and reconstruction is reduced, the aesthetic outcome is superior. Approximately 50% of IH leave behind fibrofatty tissue or damaged skin after the tumor regresses, causing a deformity.[6] Less often, children require reconstruction of damaged structures (i.e., nose, ear, lip). Staged or total excision should be considered during this period, rather than waiting for complete involution, if (1) it is clear that the patient will require resection (i.e., post-ulceration scarring, destroyed structures, expanded skin, significant fibrofatty residuum), (2) the length of the scar would be similar if the procedure was postponed to the involuted phase, or (3) the scar is in a favorable location. An advantage of operative intervention during this period, compared to late childhood, is that reconstruction is performed prior to the child's development of memory or awareness of body differences.

Involuted phase (late childhood)

Waiting until IH has fully involuted prior to resection ensures that the least amount of fibrofatty residuum and excess skin is resected, giving the smallest possible scar. Allowing full involution to occur, however, must be weighed against the psychosocial morbidity of maintaining a deformity until late childhood. Allowing full involution is advocated for lesions when it is unclear if a surgical scar would leave a worse deformity than the appearance of the residual hemangioma.

CONGENITAL HEMANGIOMA (CH)

CLINICAL FEATURES

CH is fully grown at birth and does not illustrate postnatal growth.[44–46] CH has a different appearance than IH: it is red-violaceous with coarse telangiectasias, central pallor, and a peripheral pale halo. Unlike IH, CH is more common in the extremities, has an equal sex distribution, and is almost always solitary with an average diameter of 5 cm.[44–46] Two types of CH exist: RICH and non-involuting congenital hemangioma (NICH). RICH involutes rapidly after birth and 50% of lesions have completed regression by 7 months of age.[44,46] RICH affects the head or neck (42%), limbs (52%), or trunk (6%).[44–46] RICH does not leave behind a significant adipose component, unlike IH.[46] NICH, in contrast, does not undergo involution.[42] It involves the head or neck (43%), limbs (38%), or trunk (19%).[45]

MANAGEMENT

RICH does not require operative management in infancy because it undergoes accelerated regression and is observed.

Occasionally, RICH is complicated by congestive heart failure, which is treated by beta-blockers, corticosteroid, or embolization as the lesion involutes. Since RICH undergoes such rapid natural involution, it is not clear whether the β-blockers or corticosteroid hastens involution. After regression, RICH may cause a residual deformity, usually atrophic skin and subcutaneous tissue. Operative intervention for RICH must not create a more obvious deformity than the lesion. Reconstruction with autologous grafts (fat, dermis) or acellular dermis may be indicated. NICH is rarely problematic in infancy and is observed. Because NICH is benign, asymptomatic tumors do not require excision. Symptomatic lesions in infancy are managed with embolization or resection. Resection may be indicated to improve the appearance of the affected area, as long as the surgical scar is less noticeable than the lesion. After long-term follow-up, some of these lesions are associated with pain and undergo excision at an older age. Pulse-dye laser therapy may improve the late appearance of CH by eliminating telangiectasias.

Kaposiform hemangioendothelioma

CLINICAL FEATURES

Kaposiform hemangioendothelioma (KHE) is a rare vascular neoplasm that is locally aggressive but does not metastasize.[47,48] Although one-half of lesions are present at birth, KHE may develop during infancy (58%), between age 1 and 10 years (32%), or after 11 years of age (10%).[46] KHE has an equal sex distribution, is solitary, and affects the head/neck (40%), trunk (30%), or extremity (30%).[49] The tumor is often greater than 5 cm in diameter, and thus larger than the typical IH.[48] KHE causes a visible deformity as well as pain. In addition, 50% of patients have Kassabach–Merrit phenomenon (KMP) (thrombocytopenia <25,000/mm^3, petechiae, bleeding).[47,48] KHE partially regresses after 2 years of age, although it usually persists long-term causing chronic pain and stiffness.

DIAGNOSIS

KHE is diagnosed by history and physical examination. Unlike IH, it is usually present at birth as a flat, reddish-purple, edematous lesion that does not exhibit rapid postnatal growth; it is also associated with KMP. MRI is indicated for diagnostic confirmation or to evaluate the extent of the tumor. MRI shows poorly defined margins, small vessels, and invasion of adjacent tissues.[9] KHE shows T2 hyperintensity and postgadolinium enhancement; signal voids also may be present.[9] Histologically, KHE has infiltrating sheets or nodules of endothelial cells lining capillaries.[47] Hemosiderin-filled slit-like vascular spaces with red blood cell fragments, as well as dilated lymphatics, are present.[44]

MANAGEMENT

Most lesions are large and involve multiple tissues preventing complete extirpation. Patients with KMP require systemic treatment to prevent life-threatening complications. Large, asymptomatic tumors are also managed with pharmacotherapy to minimize fibrosis and subsequent long-term pain and stiffness. KHE responds best to vincristine (90%), which is first-line therapy.[50] Recently, sirolimus, an mTOR inhibitor, has shown to be efficacious in the treatment of KHE lesions.[51] Studies comparing vincristine to sirolimus for effectiveness of treatment are ongoing. KHE does not respond as well to second-line drugs, interferon (50%) or corticosteroid (10%).[48,50] Thrombocytopenia will not be significantly improved with platelet transfusion because the platelets are trapped in the lesion. Transfusion can worsen swelling and should be avoided unless there is active bleeding or a surgical procedure is planned. By 2 years of age, the tumor often undergoes partial involution and the platelet count normalizes. Excision rarely may be indicated for symptomatic patients with well-localized lesions or who have failed chemotherapy. Resection is not required for large lesions that are not causing functional problems because KHE is benign. The risks of the resection and the resulting deformity should be weighed against the appearance of the tumor.

Pyogenic granuloma

Pyogenic granuloma (PG) has been called *lobular capillary hemangioma*.[52] PG is a solitary, red papule that grows rapidly, forming a stalk. It is small, with an average diameter of 6.5 mm; the mean age of onset is 6.7 years.[53] The male/female ratio is 2:1. PG is commonly complicated by bleeding (64.2%) and ulceration (36.3%). It primarily involves the skin (88.2%), but can involve mucous membranes as well (11.8%). PG is distributed on the head or neck (62%), trunk (19%), upper extremities (13%), or lower extremities (5%). Within the head and neck, affected sites include cheek (28.8%), oral cavity (13.5%), scalp (10.8%), forehead (9.9%), eyelids (9.0%), or lips (9.0%).[53] PG should be treated after diagnosis to prevent likely ulceration and bleeding. Numerous treatment methods have been described for PG: curettage, shave excision, laser therapy, or excision. Because the lesion can involve the reticular dermis, it may be out of the reach of the pulsed-dye laser, cautery, or shave excision. Consequently, these modalities have a recurrence rate of 43.5%.[53] Definitive treatment requires full-thickness skin excision.

VASCULAR MALFORMATIONS

Capillary malformation

CLINICAL FEATURES

Capillary malformation (CM) consists of dilated capillaries in the superficial dermis. CM is most often solitary, but can be small or extensive. It may occur in any location and over time darkens and develops fibrovascular overgrowth. It can be associated with soft tissue and skeletal hypertrophy. Sturge–Weber Syndrome consists of CM in the

ophthalmic (V1) trigeminal dermatome associated with ipsilateral ocular and leptomeningeal vascular anomalies.[54] Leptomeningeal anomalies can lead to seizures, contralateral hemiplegia, and delayed motion and cognition. Patients are at risk for retinal detachment and glaucoma and should be followed by an ophthalmologist.[6]

MANAGEMENT

Pulse-dye laser (585 nm) therapy can improve the appearance of CM by lightening the color; the head and neck region has a better response compared to the extremities.[55] Outcome also is superior for smaller lesions and those treated at a younger age.[56] Fifteen percent of patients achieve at least 90% lightening, 65% improve 50%–90%, and 20% respond poorly.[57] Multiple treatments, spaced 6 weeks apart, are often required until the CM fails to improve with additional treatments. After laser treatment, CM often redarkens over time.[58] CM also can be associated with soft-tissue and skeletal overgrowth.[54] Enlargement of the maxilla or mandible can result in an occlusal cant and malocclusion. CM of the trunk or extremity may be associated with fatty overgrowth causing asymmetry. Because overgrowth may be progressive, most patients do not require contouring, usually labial, until adolescence or adulthood. Malocclusion may be corrected in adolescence with orthodontic manipulation. If orthodontics is insufficient, an orthognathic procedure is considered when the jaws are completely grown. Severe cutaneous thickening and cobblestoning can be resected and reconstructed by linear closure, skin grafts, or local flaps. Facial asymmetry caused by overgrowth of the zygoma, maxilla, or mandible can be improved by contour burring.

LYMPHATIC MALFORMATION

CLINICAL FEATURES

Lymphatic malformation (LM) results from an error in the embryonic development of the lymphatic system. LM is characterized by the size of the malformed channels: microcystic, macrocystic, or combined.[1,3] Macrocystic lesions are defined as cysts large enough to be treated by sclerotherapy.[59] Because the lymphatic and venous systems share a common embryological origin, lymphatic-venous malformation (LVM) also can occur. LM is usually noted at birth or within the first 2 years of life. It is most commonly located on the head and neck; other frequent sites include the axilla, chest, and perineum. Lesions are soft and compressible. The overlying skin may be normal, have a bluish hue, or contain pink-red vesicles.

LM typically causes a deformity and psychosocial morbidity, especially when it involves the head and neck. The two most common complications associated with LM are bleeding and infection. Intralesional bleeding occurs in up to 35% of lesions causing bluish discoloration, pain, or swelling.[60] Infection complicates as many as 71% of LMs and can progress rapidly to sepsis.[60] Cutaneous vesicles can bleed and cause malodorous drainage as well as wounds. Swelling due to bleeding, localized infection, or systemic illness may obstruct vital structures. Two-thirds of patients with extensive cervicofacial LM require tracheostomy to maintain the airway.[60] Secondary bony overgrowth is another complication; the mandible is most commonly involved and patients can develop a malocclusion. Jaw contouring or orthognathic procedures may be required.[60] Oral lesions can cause macroglossia bleeding, pain, poor oral hygiene, and caries.[61] Thoracic or abdominal LM may lead to pleural, pericardial, or peritoneal chylous effusions. Periorbital LM leads to a permanent reduction in vision (40%), and 7% become blind in the affected eye.[62] LM may be diffuse or multifocal; patients can have splenic or osteolytic bone lesions.

DIAGNOSIS

Ninety percent of LM are diagnosed by history and physical examination.[1,3] Small, superficial lesions do not require further diagnostic workup. Large or deep lesions are evaluated by MRI to (1) confirm the diagnosis, (2) define the extent of the malformation, and (3) plan treatment. LM appears as a cystic lesion (macrocystic, microcystic, or combined) with septations of variable thickness.[63] It is hyperintense on T2-weighted sequences and does not show diffuse enhancement.[63] Although US is not as accurate as MRI, it may provide diagnostic confirmation or document intralesional bleeding. US findings for macrocystic LM include anechoic cysts with internal septations, often with debris or fluid–fluid levels.[63] Microcystic LM has ill-defined echogenic masses with diffuse involvement of adjacent tissues. Histological confirmation of LM is rarely necessary. LM shows abnormally walled vascular spaces with eosinophilic, protein-rich fluid, and collections of lymphocytes.[64] Immunostaining with the lymphatic markers D2-40 and LYVE-1 are positive.[64]

MANAGEMENT

LM is a benign condition and intervention is not mandatory; small or asymptomatic lesions may be observed. An infected LM often cannot be controlled with oral antibiotics, and intravenous antimicrobial therapy usually is required. Intervention for LM is reserved for symptomatic lesions that cause pain and significant deformity, or threaten vital structures.

Sclerotherapy

Sclerotherapy is first-line management for large or problematic macrocystic/combined LM. It involves aspiration of cysts followed by the injection of an inflammatory substance that causes scarring of the cyst walls to each other. Sclerotherapy has superior efficacy and a lower complication rate than resection.[65] Resection of macrocystic LM generally is not necessary unless (1) the lesion is symptomatic and sclerotherapy is no longer possible because all of the macrocysts have been treated, (2) resection may be curative because the lesion is small and well localized,

or (3) the lesion is so massive or has a large microcystic component such that a significant mass will remain after sclerotherapy.

Several scleroscents may be used to treat LM: doxycycline, sodium tetradecyl sulfate (STS), ethanol, bleomycin, and OK-432. We prefer doxycycline because it is very effective (83% reduction in size) and safe (less than 10% risk of skin ulceration).[63,66] STS is our second-line agent. Ethanol is an effective scleroscent but has the highest complication rate. It can be used for small lesions, but large volumes should be avoided to reduce the risk of local and systemic toxicity. Ethanol can injure nerves and thus should not be used in proximity to important structures. The use of OK-432 is limited because it is not widely available in all countries.[65]

The most common complication of sclerotherapy for LM is skin ulceration (10%).[63,66] Ethanol is associated with additional systemic toxicity: CNS depression, pulmonary hypertension, hemolysis, thromboembolism, and arrhythmias.[63] Extravasation of the scleroscent into muscle can cause atrophy and contracture.[55] LM often re-expands over time; 9% recur within 3 years following OK-432 treatment, and most will re-expand with longer follow-up.[65,67] Consequently, patients often need repeat sclerotherapy over the course of their lifetime. If a problematic LM recurs and macrocysts are no longer present in the lesion, then resection is a treatment option.

Resection

Extirpation of LM can be associated with significant morbidity: major blood loss, iatrogenic injury, and deformity.[60,61,68] For example, resection of cervicofacial LM can injure the facial nerve (76%) or hypoglossal nerve (24%).[60] Excision is usually subtotal because LM involves multiple tissue planes and important structures; "recurrence" thus is common (35–64%).[67,69] Consequently, sclerotherapy is the preferred treatment for macrocystic/combined lesions. Nonproblematic microcystic lesions can be observed. Resection is reserved for (1) symptomatic microcystic LM causing bleeding, infection, obstruction/destruction of vital structures, or significant deformity; (2) symptomatic macrocystic/combined LM that no longer can be managed with sclerotherapy because all macrocysts have been treated; and (3) small, well-localized LM (microcystic or macrocystic) that may be completely excised for cure. When considering resection, the postoperative scar/deformity following removal of the LM should be weighed against the preoperative appearance of the lesion.

For diffuse malformations, staged resection of defined anatomic areas is recommended. Subtotal resections of problematic areas, such as bleeding vesicles or an overgrown lip, should be carried out rather than an attempting "complete" excision of a benign lesion, which would result in a worse deformity than the malformation itself. Macroglossia may require tongue reduction to return the tongue to the oral cavity or to correct an open-bite deformity. Bony overgrowth is corrected by osseous contouring, and malocclusion may require orthognathic correction, usually at the time of skeletal maturity.

Bleeding or leaking cutaneous vesicles may be managed by resection if they are localized, and the wound can be closed by direct approximation of tissues. Vesicles often recur through the scar. Large areas of vesicular bleeding or drainage are best managed by sclerotherapy or carbon dioxide laser; alternatively, wide resection and skin graft coverage are required. Microcystic vesicles involving the oral cavity respond well to radiofrequency ablation.[70] Patients and families are counseled that LM can expand following any intervention, and thus additional treatments may be required in the future.

Venous malformation

CLINICAL FEATURES

Venous malformation (VM) results from an error in vascular morphogenesis; veins are dilated with thin walls and abnormal smooth muscle.[71] Consequently, lesions expand, flow stagnates, and clotting occurs. Lesions are blue, soft, and compressible; hard calcified phleboliths may be palpable. VM may range from small, localized skin lesions to diffuse malformations involving multiple tissue planes and vital structures. VM is typically sporadic and solitary in 90% of patients; 50% have a somatic mutation in the endothelial receptor TIE2.[72,73] Sporadic VM is usually greater than 5 cm (56%), single (99%), and located on the head/neck (47%), extremities (40%), or trunk (13%).[72] Almost all lesions involve the skin, mucosa, or subcutaneous tissue; 50% also affect deeper structures (i.e., muscle, bone, joints, viscera).[72]

Approximately 10% of patients with VM have multifocal, familial lesions: either glomuvenous malformation (GVM) or cutaneomucosal VM (CMVM).[72,74] GVM is an autosomal dominant condition with abnormal smooth muscle-like glomus cells along the ectatic veins. It is caused by a loss-of-function mutation in the glomulin gene.[75] Lesions are typically multiple (70%), small (two-thirds <5 cm), and located in the skin and subcutaneous tissue; deeper structures are not affected.[72] GVM involves the extremities (76%), trunk (14%), or head/neck (10%). Lesions are more painful than typical VM. CMVM are small, multifocal mucocutaneous lesions caused by a gain-of-function mutation in the TIE2 receptor.[76] The condition is autosomal dominant and less common than GVM. Lesions are small (76% <5 cm), multiple (73%), and located on the head/neck (50%), extremity (37%), or trunk (13%).[72] Blue rubber bleb nevus syndrome (BRBNS) is a rare condition with multiple, small (<2 cm) VM involving the skin, soft tissue, and gastrointestinal tract.[77] Morbidity is associated with gastrointestinal bleeding requiring chronic blood transfusions or recurrent, usually self-limited, intussusceptions.

Complications of VM include psychosocial morbidity, pain, and swelling. Head and neck VM may present with mucosal bleeding or progressive distortion leading to airway or orbital compromise. Extremity VM can cause

leg-length discrepancy, hypoplasia due to disuse atrophy, pathologic fracture, hemarthrosis, and degenerative arthritis.[68] VM of muscle may result in fibrosis and subsequent pain and disability. A large VM involving the deep venous system is at risk for thrombosis and pulmonary embolism. Gastrointestinal VM can cause bleeding and chronic anemia. Stagnation within a large VM results in a localized intravascular coagulopathy (LIC) and painful phlebothromboses.

DIAGNOSIS

At least 90% of VMs are diagnosed by history and physical examination.[1,3] Dependent positioning of the anomaly can help confirm the diagnosis; VM will enlarge because of reduced venous return. Small, superficial VMs do not require further diagnostic workup. However, large or deeper lesions are evaluated by MRI to (1) confirm the diagnosis, (2) define the extent of the malformation, and (3) plan treatment. VM is hyperintense on T2-weighted sequences.[63] In contrast to LM, VM enhances with contrast, often shows phleboliths as signal voids, and is more likely to involve muscle. US may be used for some localized lesions; findings include compressible, anechoic–hypoechoic channels separated by more solid regions of variable echogenicity.[8] Phleboliths are hyperechoic with acoustic shadowing.[63] Computerized tomography (CT) is occasionally indicated to assess osseous VM. Histological diagnosis of VM is rarely necessary, but may be indicated to rule out malignancy or if imaging is equivocal.

MANAGEMENT

Patients with large extremity lesions are prescribed custom-fitted compression garments to reduce blood stagnation in the lesion and thus the risk of expansion, LIC, phlebolith formation, and pain.[78] Patients with recurrent pain secondary to phlebothrombosis may find relief from prophylactic daily aspirin (81 mg) to prevent thrombosis. Large lesions are at risk for coagulation of stagnant blood, stimulation of thrombin, and conversion of fibrinogen to fibrin. Fibrinolysis results in LIC.[78] The chronic consumptive coagulopathy can cause either thrombosis (phleboliths) or bleeding (hemarthrosis, hematoma, intraoperative blood loss).[78] Low molecular weight heparin (LMWH) is considered for patients with significant LIC or at risk for disseminated intravascular coagulation (DIC).[78] Patients with significant coagulopathy will need prophylactic treatment with LMWH prior to any significant surgical or interventional procedure. Patients who develop a serious thrombotic event require long-term anticoagulation or a vena caval filter.

Sclerotherapy

Intervention for VM is reserved for symptomatic lesions that cause pain and deformity, or threaten vital structures. First-line treatment is sclerotherapy, which is safer and more effective than resection.[59,63,79] Diffuse malformations are managed by targeting specific symptomatic areas, because the entire lesion is too extensive to treat at one time. Sclerotherapy is continued until symptoms are alleviated or when vascular spaces are no longer present to inject. Although sclerotherapy effectively reduces the size of the lesion and improves symptoms, it does not remove the malformation. Consequently, patients may continue to have a mass or visible deformity after treatment that may be improved by resection. In addition, VM usually re-expands after sclerotherapy, and thus patients often require additional sclerotherapy treatments over the course of their lifetime.

Our preferred scleroscents are STS and ethanol; STS is most commonly used.[63] Although ethanol is more effective than STS, it has a higher complication rate. Most patients, especially children, are managed under general anesthesia using US and/or fluoroscopic imaging. The most common local complication of sclerotherapy for VM is skin ulceration (10%–15%).[59,79] Extravasation of the scleroscent into muscle can cause atrophy and contracture.[59] Post-treatment swelling may necessitate close monitoring. Systemic adverse events from sclerotherapy, including hemolysis, hemoglobinuria, and DIC, are more common if large lesions are treated. Patients with low fibrinogen levels are given LMWH 14 days before and after the procedure.[78] Anticoagulation is held for 24 hours perioperatively (12 hours before and after the intervention) to prevent bleeding complications.[63,78]

Resection

Extirpation of VM can be associated with significant morbidity: major blood loss, iatrogenic injury, and deformity. In contrast to sclerotherapy, resection is not favorable because (1) the entire lesion can rarely be removed, (2) resection may cause a worse deformity than the lesion, (3) the risk of recurrence is high because channels adjacent to the visible lesion are not treated, and (4) the risk of blood loss and iatrogenic injury is greater. Resection should be considered for (1) small, well-localized lesions that can be completely removed, (2) persistent mass or deformity after completion of sclerotherapy (patent channels are not accessible for further injection), or (3) large lesions unlikely to reduce substantially with extensive sclerotherapy. When considering resection, the postoperative scar/deformity following removal of the VM should be weighed against the preoperative appearance of the lesion. Subtotal resections of problematic areas, such as an overgrown lip, should be carried out rather than attempting "complete" excision of a benign lesion, which would result in a worse deformity than the malformation itself. Patients and families are counseled that VM can expand following excision, and thus additional operative intervention may be required in the future.

Many VMs should have sclerotherapy prior to operative intervention. After adequate sclerotherapy, the VM is replaced by scar, and thus the risk of blood loss, iatrogenic injury, and recurrence is reduced. In addition, fibrosis facilitates resection and reconstruction. Very large

lesions unlikely to respond to sclerotherapy should only be resected in experienced centers as massive rapid exsanguination is to be anticipated intraoperatively. Because GVM are usually small and less amenable to sclerotherapy, first-line therapy for painful lesions often is resection. Nd:YAG photocoagulation may be an adjuvant to sclerotherapy for the management of difficult airway lesions.[80] Gastrointestinal VM with chronic bleeding, anemia, and transfusion requirements are typically managed by resection. Endoscopic banding or sclerotherapy can treat solitary lesions.[81] Multifocal lesions (i.e., BRBNS) require removal of as many lesions as possible. In the gastrointestinal tract, multiple enterotomies, instead of bowel resection, is performed to preserve bowel length.[77,81] Diffuse, problematic colorectal VM may require colectomy, anorectal mucosectomy, and endorectal pull-through.[82]

Arteriovenous malformation

CLINICAL FEATURES

AVM results from an error in vascular development during embryogenesis. An absent capillary bed causes shunting of blood directly from the arterial to venous circulation, through a fistula (direct connection of an artery to a vein) or nidus (abnormal channels bridging the feeding artery to the draining veins).[71] Genetic abnormalities cause certain types of familial AVM. Hereditary hemorrhagic telangiectasia is due to mutations in endoglin and activin receptor-like kinase 1 (ALK-1), which affect transforming growth factor-beta (TGF-β) signaling.[83] Capillary malformation–AVM (CM-AVM) results from a mutation in RASA1.[84] Patients with PTEN mutations also can develop arteriovenous anomalies.[85]

The most common sites of extracranial AVM are the head and neck, followed by the limbs, trunk, and viscera.[6] Although present at birth, AVM may not become evident until childhood. Arteriovenous shunting reduces capillary oxygen delivery causing ischemia; patients are at risk for pain, ulceration, bleeding, and congestive heart failure. AVM also may cause disfigurement, destruction of tissues, and obstruction of vital structures. AVM worsens over time and can be classified according to the Schobinger staging system (Table 85.2).[86]

Table 85.2 Schobinger staging of AVM

Stage	Clinical findings
I (quiescence)	Warm, pink-blue, shunting on Doppler
II (expansion)	Enlargement, pulsation, thrill, bruit, tortuous veins
III (destruction)	Dystrophic skin changes, ulceration, bleeding, pain
IV (decompensation)	Cardiac failure

DIAGNOSIS

Most AVMs are diagnosed by history and physical examination.[1,3] If AVM is suspected, the diagnosis should be confirmed by US with color Doppler examination showing fast flow and shunting. MRI also is obtained to (1) confirm the diagnosis, (2) determine the extent of the lesion, and (3) plan treatment. MRI shows dilated feeding arteries and draining veins, enhancement, and flow voids on T2-weighted imaging.[87] If the diagnosis remains unclear after US and MRI, angiography is performed. Angiography also is indicated if embolization or resection is planned to determine the flow dynamics of the lesion. AVM shows tortuous, dilated, arteries with venous shunting and dilated draining veins on angiogram.[87] Often, a blush illustrates the nidus of the lesion. Histopathological diagnosis of AVM is rarely necessary, but may be indicated to rule out malignancy or if imaging is equivocal.

MANAGEMENT

Because AVM is often diffuse, involving multiple tissue planes and important structures, cure is rare. The goal of treatment usually is to *control* the malformation. Intervention is focused on alleviating symptoms (i.e., bleeding, pain, ulceration), preserving vital functions (i.e., vision, mastication), and improving a visible deformity. Management options include embolization, resection, or a combination. Resection offers the best chance for long-term control, but the re-expansion rate is high and extirpation may cause a worse deformity than the malformation itself.[88]

Embolization or incomplete excision of an asymptomatic lesion may stimulate it to enlarge and become problematic. Intervention is determined by (1) the size and location of the AVM, (2) the age of the patient, and (3) Schobinger stage. Although resection of an asymptomatic Stage I AVM offers the best chance for long-term control or "cure," intervention must be individualized based on the degree of deformity that would be caused by excision and reconstruction.[88] For example, a large Stage I AVM in a non-anatomically important location (i.e., trunk, proximal extremity) may be resected without consequence, before it progresses to a higher stage where resection is more difficult, and the recurrence rate is greater.[88] Similarly, a small, well-localized AVM in a more difficult location (i.e., face, hand) may be excised for possible "cure" before it expands and complete extirpation is no longer possible.

In contrast, a large, asymptomatic AVM located in an anatomically sensitive area is best observed, especially in a young child not psychologically ready for major resection and reconstruction. First, resection and reconstruction may result in a more noticeable deformity or functional problem than the malformation itself. Second, although the recurrence rate is lower when Stage I AVM is resected, it is still high, and thus, even after major resection and reconstruction, the malformation can recur. Third, some children (17.4%) do not experience significant morbidity from their lesion long term into adulthood.[88]

Intervention for Stage II AVMs is similar to Stage I lesions. However, the threshold for treatment is lower if an enlarging lesion is causing a worsening deformity or if functional problems are expected. Stage III and IV AVMs require intervention to control pain, bleeding, ulceration, or congestive heart failure.

Embolization

Embolization involves the delivery of a substance, through a catheter to the AVM, to occlude blood flow and/or fill a vascular space. Reduced arteriovenous shunting and ischemia improve symptoms and may shrink the lesion. Embolization is used either as a preoperative adjunct to resection or as monotherapy for lesions not amenable to extirpation. Because the AVM is not removed, almost all lesions eventually will expand after treatment.[71,86–89] Stage I AVM has a lower recurrence rate than higher-staged lesions. Most recurrences occur within the first year after embolization, and in an earlier era, 98.0% re-expanded within 5 years.[88] Despite the high likelihood of re-expansion, embolization can effectively palliate an AVM by reducing its size, slowing expansion, and alleviating pain and bleeding. Preoperative embolization also reduces blood loss during extirpation. In recent years, embolization from the venous outflow approach, sometimes in combination with nidus embolization from the arterial side, has offered significantly improved outcomes. Long-term outcome data are not yet available, but there is significant optimism that this approach will allow earlier and more effective embolization.

Substances used for embolization may be liquid [n-butyl cyanoacrylate (n-BCA), ethanol, Onyx (ethylene-vinyl alcohol copolymer)] or solid [polyvinyl alcohol particles (PVA), coils]. The goal of embolization is occlusion of the nidus and proximal venous outflow.[87] The embolic material is delivered to the nidus, *not* the arterial feeding vessels. Occlusion of inflow will cause collateralization and expansion of the AVM; access to the nidus also will be blocked preventing future embolization. For preoperative embolization, temporary occlusive substances (gelfoam powder, PVA, embospheres) that undergo phagocytosis are used. Permanent liquid agents capable of permeating the nidus (ethanol, n-BCA, Onyx) are used when embolization is the primary treatment. The most frequent complication of embolization is ulceration.

Resection

Resection of AVM has a lower recurrence rate than embolization and is considered for well-localized lesions or to correct focal deformities (i.e., bleeding or ulcerated areas, labial hypertrophy).[88] Wide extirpation and reconstruction of large, diffuse AVM should be exercised with caution because (1) cure is rare and the recurrence rate is high, (2) the resulting deformity is often worse than the appearance of the malformation, and (3) resection is associated with significant blood loss, iatrogenic injury, and morbidity. When excision is planned, preoperative embolization will facilitate the procedure by reducing the size of the AVM, minimizing blood loss, and creating scar tissue to aid the dissection. Multiple embolizations, spaced 6 weeks apart, may be required prior to resection. Excision should be carried out 24–72 hours after embolization, before recannalization restores blood flow to the lesion.

Surgical margins are best determined clinically, by assessing the amount of bleeding from the wound edges.[86] Most defects can be reconstructed by advancing local skin flaps. Skin grafting ulcerated areas have a high failure rate because the underlying tissue is ischemic; excision with regional flap transfer may be required. Free-flap reconstruction permits wide resection and primary closure of complicated defects, but does not improve long-term AVM control.[68,86,88–90] Despite subtotal and presumed "complete" extirpation, most AVMs treated by resection recur.[88] The majority of recurrences occur within the first year after intervention, and 86.6% re-expand within 5 years of resection.[88] Patients and families are counseled that AVM is likely to re-expand following resection, and thus, additional treatment may be required in the future.

PTEN-ASSOCIATED VASCULAR ANOMALY

The PTEN (phosphatase and tensin homologue) gene encodes a tumor suppressor lipid phosphatase.[91] Patients with PTEN mutations have PTEN hamartoma-tumor syndrome (PHTS). This autosomal dominant condition had previously been referred to as Cowden syndrome or Bannayan–Riley–Ruvalcaba syndrome (BRRS).[85,92] Males and females are equally affected, and approximately one-half (54%) of patients have a unique fast-flow vascular anomaly with arteriovenous shunting, referred to as a PTEN-associated vascular anomaly (PTEN-AVA).[85] Unlike typical AVM, PTEN-AVA may be multifocal, is associated with ectopic adipose tissue, and has disproportionate, segmental dilation of the draining veins.[85,87] Patients with PHTS have macrocephaly, and males have penile freckling.[85] Histopathology shows skeletal muscle infiltration with adipose tissue, fibrous bands, and lymphoid aggregates. In addition, tortuous arteries with transmural muscular hyperplasia and clusters of abnormal veins with variable smooth muscle are present.[85] Genetic testing is confirmative; the mutation is associated with multiple benign and malignant tumors, which require surveillance.

Combined vascular malformations

CAPILLARY MALFORMATION–ARTERIOVENOUS MALFORMATION

The prevalence of CM-AVM is estimated to be 1 in 100,000 Caucasians.[84,93] Patients have atypical CMs that are small, multifocal, round, pinkish-red, and surrounded by a pale halo (50%).[84,93] Thirty percent of individuals also have an AVM: Parkes Weber syndrome (PWS) (12%), extracerebral AVM (11%), or intracerebral AVM (7%).[93] PWS describes

a diffuse AVM of an overgrown extremity with an overlying CM.[6] PWS involves the lower extremity approximately twice as often as the upper extremity.[93] CM-AVM is an autosomal dominant condition caused by a loss-of-function mutation in the *RASA1* gene.[84] A patient presenting with multiple CMs, especially with a family history of similar lesions, should be evaluated for possible AVMs on physical examination. Because 7% of patients with CM-AVM will have an intracranial fast-flow lesion, brain MRI should be considered.[74] Exploratory imaging of other anatomical areas is not necessary because extracranial AVMs have not been found to involve the viscera.[93] Although the CM is rarely problematic, associated AVMs can cause significant morbidity.

KLIPPEL–TRENAUNAY SYNDROME

Klippel–Trenaunay syndrome (KTS) is an eponym denoting a slow-flow, capillary-lymphatico-venous malformation (CLVM) in association with soft tissue and/or skeletal overgrowth.[94] KTS affects the lower extremity in 95% of patients, the upper extremity in 5% of patients, and least commonly the trunk.[94] Leg-length discrepancy is followed by plain radiographs, and MRI is used to confirm diagnosis as well as determine the extent of the anomalies. The deep venous system is commonly malformed. The marginal vein of Servelle is often located in the lateral calf and thigh and communicates with the deep venous system.[95] Complications include thrombophlebitis (20%–45%) and pulmonary embolism (4%–24%).[96] KTS of the lower extremity can involve the pelvis causing hematuria, hematochezia, constipation, and bladder outlet obstruction. Unlike some other hemihypertrophy syndromes, patients with KTS are not at increased risk for Wilms' tumor, and screening ultrasounds are unnecessary.[97] Severe enlargement of the foot requires ray, midfoot, or Syme amputation to allow the use of footwear. Management of the VM component of KTS is conservative with compressive stockings for insufficiency and aspirin to minimize phlebothrombosis. Symptomatic varicose veins may be removed or sclerosed if a functioning deep system is present. Occasionally, sclerotherapy and surgical excision are necessary for the LM component. Staged contour resection of the extremity can be performed.

CLOVEs SYNDROME

CLOVE syndrome is an overgrowth condition associated with congenital lipomatous overgrowth, vascular malformations, and epidermal nevi in a very distinct phenotype. This cohort of patients has characteristic features of truncal lipomatous overgrowth in combination with vascular anomalies, including capillary, lymphatic, venous, and arteriovenous. In addition, deformities of the extremities include wide feet and hands, macrodactyly, and a wide sandal gap. Scoliosis and renal issues are also seen, with a potential increase risk in the development of Wilms' tumors.[98] Genetic analysis of these patients demonstrates a somatic mutation in the PI3 kinase pathway.[99]

New medical treatments

In 2011, Hammill et al. published a case series of complicated vascular lesions treated with the mTOR inhibitor sirolimus. The lesions treated included KHE and complicated lymphatic or combined lymphatico-venous malformations.[51] mTOR is found in the PI3 kinase pathway, and complicated vascular lesions, especially lymphatic lesions, have been shown to have PIK3CA mutations.[100,101] There have been multiple other case series of lymphatic and complex combined vascular malformations being treated with sirolimus resulting in improved symptoms, quality of life, and bulk of the lesion. In a recent study of 53 patients with complex vascular malformations, 85% had improvement in quality of life and a partial response in the bulk of their disease (radiologically and clinically).[102]

Other pharmacologic agents that have been used to treat complex vascular lesions include propranolol and sildenafil. Similar to hemangioma treatment, propranolol is proposed to inhibit angiogenesis and induce apoptosis. Sildenafil, alternatively, is proposed to work on vascular endothelial growth factor inhibition.[103] These agents have not achieved widespread acceptance for treating vascular anomalies.

In AVMs, doxycycline has shown some promise in stabilization of the lesion. There are also reports of improved symptoms, especially pain. Doxycycline is a nonspecific matrix metalloproteinase (MMP) inhibitor, and high levels of MMP have been found in AVM tissue.[104]

Congenital nevi

LEE W. T. ALKUREISHI AND BRUCE S. BAUER

INTRODUCTION

Congenital nevi are a group of skin lesions occurring at birth or becoming apparent within the first several years of life, and are characterized by ectopic rests of dermal elements. Although most commonly melanocytic in nature, nevi may also originate from sebaceous, neural, or epidermal elements. Lesion characteristics vary according to the type of cell involved, location within the skin, and level of cell differentiation. Knowledge of the differential diagnosis and natural history of these lesions can help balance the plan of care, in order to address the potential risk of malignant degeneration while accounting for functional and aesthetic concerns encountered in the course of excision and reconstruction. This chapter outlines the presentation and management of congenital nevi, with special emphasis on congenital melanocytic nevi (CMNs).

CONGENITAL MELANOCYTIC NEVI

CMNs are the most common congenital nevi and are composed of cells of melanocytic origin that carry a varying amount of pigment. These are usually present at birth, though a small percentage may not initially be evident due to a lack of pigment production. These "tardive" CMNs are usually noted within the first 2 years of life. The presentation of CMN varies from very small, relatively insignificant nevi to giant disfiguring lesions covering large portions of the body, with significant implications in terms of the risk of melanoma, central nervous system involvement, and other associated conditions, in addition to the significant aesthetic deformity. The natural history of CMN, true melanoma risk, and optimal treatment algorithms remain controversial topics within the literature.

Epidemiology

The overall incidence of CMN is estimated to be 1%–6% of live births, with larger lesions being much less common. Small lesions (<1.5 cm projected adult size [PAS]) are reported to occur in 1:100 births, intermediate (1.5–20 cm) lesions in 1:1,000, large (>20 cm) lesions in 1:20,000 births, and giant (>50 cm) lesions in 1:500,000.[1–3] The incidence of CMN is slightly higher in infants of Japanese and African American descent[2,4] and has a female-to-male ratio of 3:2.[5] CMNs are most commonly located on the trunk (38%), extremities (38%), head and neck, (14%) and feet and hands (10%).[6]

Etiology

Embryologically, melanocytes originate from neural crest cells as melanoblasts and migrate to the basal layer of the epidermis between the 5th and 24th week of gestation. They differentiate into dendritic melanocytes and form melanosomes, which produce pigment for transfer to keratinocytes. CMNs result from a disturbance in this migration and differentiation process, producing ectopic rests of immature cells along their course of migration.[7] As a result, nevus cells often extend deep into the subcutaneous tissues and can involve fascia, muscle, periosteum, or the leptomeninges, a condition known as neurocutaneous melanosis (NCM).

It is believed that disturbances in the melanoblast migration pathway may be related to overexpression of the proto-oncogenes *c-met* and/or *c-kit*, which produce tyrosine kinase receptors binding hepatocyte growth factor/scatter factor (HGF/SF) and stem cell factor (SCF), respectively.[8] *C-met* and *c-kit* (via the N-ras oncogene) have also been implicated in the development of rhabdomyosarcoma and melanoma in patients with large CMN (LCMN).[9,10]

Pathology

In contrast with normal melanocytes, nevus cells tend to group together in clusters and assume a rounded rather than dendritic shape. They also retain pigment within their cytoplasm instead of transferring it to the surrounding keratinocytes.[11]

Because of the higher risk of malignant transformation found in CMN compared to acquired nevi, efforts have been made to identify histologic characteristics specific to CMN. Nevus cells found within eccrine ducts, follicular epithelium, or blood vessels indicate congenital lesions; however, not all CMNs display this finding.[12] Furthermore, only congenital lesions demonstrate nevus cells within the deeper subcutaneous tissues, fascia, and/or muscle. Clinically, examination of small CMN with a dermatoscope or under loupe magnification will reveal small pigment granules at the peripheral aspect of the lesion, another specific finding to CMN.[13] Discovery of more specific markers for CMN will help to more clearly determine the true rate of melanoma associated with these lesions.

Presentation

The clinical features of CMN can differ greatly in terms of size and appearance (Figure 86.1). All CMNs are present at birth, though tardive CMN may not be visible until production of melanin increases within the first 1–2 years of life. Coloration varies from pale tan to a deep bluish black, and may be uniform or extremely variegated. The lesions are often thickened in texture with increased skin markings compared to surrounding normal skin, and may have a nodular or rugous quality. They often have hair, which can range from fine light fuzz to coarse thick follicles. When large lesions are present, they may be accompanied by smaller peripheral satellite lesions of different sizes and numbers, which may appear for the first 2–3 years of life.

In general, CMNs tend to grow in proportion with the child. The surface of CMN can become more verrucous and irregular with darkening pigmentation; however, lightening of color can also be seen in as many as 30% of patients with large and giant nevi.

Most CMNs are asymptomatic, but symptoms can include pruritus, tenderness, xerosis, and/or skin erosion or breakdown related to relative paucity of subcutaneous fat and sweat glands underlying the CMN. Skin erosion is not uncommon in the neonatal period but may also occur later. This does not necessarily indicate malignant change but warrants further investigation.

Classification

The highly variable presentation of CMN has important implications with regard to determination of malignancy risk, potential development of NCM, and treatment planning. Several authors have proposed classification schemes for CMN, the majority of which use the PAS of the nevus as the principle category.[14] The PAS can be determined by multiplying the largest diameter of the lesion in infancy by a predetermined factor, which varies by body area (Table 86.1).[16] As a general rule, a 12 cm lesion on the head or neck or 7 cm lesion on the body of an infant will grow to meet the large nevi classification (>20 cm PAS).[15] Another cited definition of large congenital nevi includes lesions >2% total body surface area.[1]

[b] Factor that should be multiplied by the CMN diameter in infancy to obtain its estimated size in adulthood

Comparison of study outcomes, however, has thus far been limited by inconsistent nomenclature and categorization, a finding that has become increasingly important with the development of LCMN registries pooling data from multiple institutions.[5,17] In addition to projected size, clinical features such as color variegation, localization, rugosity, hypertrichosis, and number of satellite lesions may prove equally important markers for adverse outcomes in CMN patients.[18,19] In an attempt to address these issues, Krendel and Marghoob[14] created a more inclusive classification system based on expert consensus. This classification is presented in Table 86.2.

Malignancy risk

MELANOMA

An immediate concern of the family and doctors involved with the care of these patients is the potential risk of malignancy, primarily malignant melanoma. Melanoma may arise within the nevus or in extracutaneous sites, most commonly the central nervous system. Earlier studies reporting the incidence of melanoma varied widely from 0% to 40%[1,2,20–23]; however, it is generally held that these studies may have overestimated this risk as a result of small sample sizes, selection bias, and/or overdiagnosis.[24] Nevertheless, there remains a significantly elevated risk of melanoma in CMN patients, which must be a consideration in treatment planning.

At this time, the true incidence of melanoma in CMN patients is difficult to ascertain. Heterogeneity of the patient population, lack of standardized nomenclature, and multiple treatment modalities all contribute to difficulty in determining the true natural history of CMN. However, recent literature reviews and meta-analyses have helped elucidate this to some degree.[24,25] The lifetime risk of developing melanoma, cutaneous or extracutaneous, appears likely to be less than 5% for all patients with LCMN[26] and as low as 0.7%–2% for smaller lesions.[24,25] However, it is important to note that many of the patients included in these studies have undergone partial or complete excision of their nevi, potentially underestimating the true risk of melanoma. Factors shown to be associated with an increased risk of melanoma include larger nevus size, truncal location, and the presence of multiple satellite lesions.[5,23]

The risk of melanoma arising within small CMNs before puberty is felt to be extremely unlikely.[27] However, this does not hold true for LCMN and giant CMN (GCMN). It has been reported that 50% of LCMNs that develop malignancy do so in the first 3 years of life, with 60% by childhood and 70% by puberty.[16] In a review of 289 patients with LCMN, DeDavid et al.[15] found 67 cases of melanoma, of which 34 (51%) arose within the nevus. Twenty-one cases (31.3%) developed melanoma within the CNS, and two patients (3%) developed cutaneous melanoma beyond the nevus margins. The remaining 10 patients (15%) presented with metastatic disease and an unknown primary site. It is also important to note that there has only been one reported case of melanoma developing within a satellite lesion, in a patient with CMN and neurofibromatosis type I.[5]

OTHER TUMORS ASSOCIATED WITH CMN

In addition to melanoma, patients with CMN may be at risk for the development of other tumors, both benign and malignant. These include lipomas and schwannomas, sarcomas, malignant cellular blue nevus, and undifferentiated spindle cell neoplasms.[28]

Patient evaluation

HISTORY AND PHYSICAL EXAMINATION

On initial history, any changes in the appearance of the nevus or satellite lesions should be elicited, along with any family history of melanoma. Documentation of developmental milestones and presence of any neurologic symptoms should be noted. Serial examination of the lesion(s) should be undertaken every 3–6 months, depending on the character of and variability in the lesion's appearance.

Patches of darker color or raised nodules can develop within LCMN and may represent neural nevus. This is a form of intradermal nevus, with melanocytes that appear histologically similar to Schwann cells and contain nerve organelles such as Meissner and Pacinian corpuscles. The patches may also represent local areas of proliferation that do not necessarily behave in an aggressive manner. Biopsy of any suspicious raised, ulcerating, or atypical areas can be used to exclude malignancy (Figure 86.2). Histologic findings of low mitotic rate, lack of necrosis, evidence of maturation in the cell population, and lack of high-grade nuclear atypia are clues to a benign course. The best description of these areas is melanocytic tumor of uncertain potential, and these unusual areas are best addressed earlier in the course of reconstruction.

In older children and adolescents, there can also be psychological implications associated with the diagnosis of LCMN or GCMN. In one study of 29 patients, 30% were found to have emotional, behavioral, or social problems. The reasons for this

Table 86.2 New classification of congenital melanocytic nevi

CMN parameter	Terminology	Definition
CMN project adult size	"Small CMN"	<1.5 cm
	"Medium CMN"	
	"M1"	1.5–10 cm
	"M2"	>10–20 cm

are likely multifactorial, including concerns regarding malignant change, appearance of the nevus or postsurgical scarring, and anxiety related to treatment itself.[29]

NCM AND MAGNETIC RESONANCE IMAGING

The clinical presentation of NCM can range from asymptomatic to progressive, severe neurologic deterioration with developmental delay, hydrocephalus, and seizures, often with fatal outcomes. Symptoms may be caused by blockage of cerebrospinal fluid circulation by benign nevus cell proliferation, leading to hydrocephalus and increased intracranial pressure, or from malignant degeneration.

If NCM is to become symptomatic, the vast majority of cases will do so before age 3 years. The prognosis of symptomatic NCM is poor, with >90% dying within 3 years of onset of neurologic symptoms.[30] It is difficult to know the true incidence of NCM in association with LCMN, as screening of asymptomatic patients is not universally performed. However, a study of an Internet registry found NCM on magnetic resonance imaging (MRI) in approximately 5% of patients with LGCM/GCMN. Of these, only 5%–6% became symptomatic.[31] LCMN of the posterior midline and those found in association with multiple satellite nevi (greater than 20) have the highest risk of NCM and should be strongly considered for MRI screening (Figure 86.1a,b).[32]

MRI is the study of choice for detection of melanin involving the leptomeninges, which is seen as focal shortening of T1 relaxation time and, less frequently, T2 relaxation time. For increased sensitivity, the MRI should be obtained prior to age 4 months, because after that time, increasing

Figure 86.2 Sarcoma arising within a giant congenital melanocytic nevus at birth.

myelination of the CNS can potentially obscure visualization of nevus cells.[33]

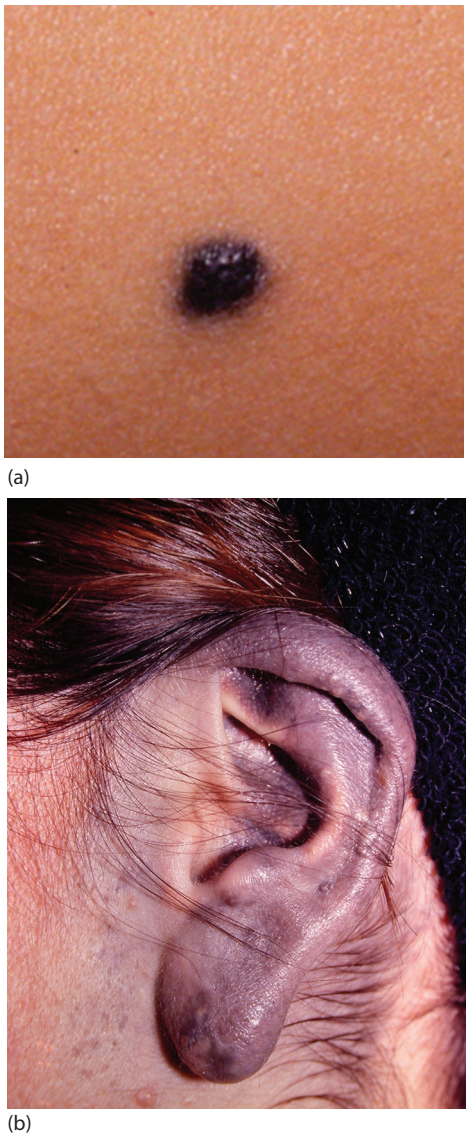
It is important to convey that the finding of NCM on MRI does not necessarily imply the future development of neurologic symptoms. It does, however, indicate a risk for later development of benign or malignant melanotic tumors. Foster et al.[34] reported that 23% of at risk-patients had NCM on MRI imaging, with only one patient developing neurologic sequelae of hypotonia, developmental delay, and seizures during the 5-year follow-up period. More recent studies report a lower 5% incidence of NCM in patients with LCMN.[31]

In cases of symptomatic NCM, the associated poor prognosis should deter the surgeon from aggressive management of the cutaneous lesion. However, the low reported incidence of progression from asymptomatic to symptomatic NCM cautions against applying that same philosophy to this patient population. Further study will help to fully ascertain the true predicted course of disease in asymptomatic, scan-positive patients and help guide both surgical planning and the role of serial scanning. At this time, if the initial MRI is positive, we proceed with reconstruction as planned and feel that further scans are unnecessary unless neurologic symptoms develop.

Differential diagnosis

BLUE NEVI

Blue nevi are smooth, bluish-black lesions that can be present at birth but more commonly appear during childhood and puberty (Figure 86.3). They occur more frequently in females and are usually found on the head or extremities. Two variants exist: common and cellular. The common blue nevus is a relatively small (<1 cm), sharply demarcated, dome-shaped benign lesion. Histologically, it composed of intradermal and possibly subcutaneous dendritic melanocytes with normal overlying epithelium. The cellular blue



(a)

(b)

Figure 86.3 Blue nevus **(a)** Typical appearance. **(b)** Extensive blue nevus involving the external ear.

nevus is larger (1–3 cm) with less regular borders and is frequently found in the lumbosacral area. The lesion tends to be wider at the surface than at the base and is composed of spindle-shaped melanocytes in aggregates mixed within dendritic melanocytes. Unlike the common form, malignant transformation has been reported within the cellular variant, and therefore, excision is recommended.

MONGOLIAN SPOTS

Mongolian spots are blue-gray macules, usually overlying the lumbosacral area of otherwise healthy infants (Figure 86.4). They are more common in Asian and darker-skinned individuals. Mongolian spots are most often present at birth but may appear within the first weeks of life, and usually regress spontaneously by age 3–4 years of age. Lesions are made up of widely scattered dendritic melanocytes within the lower two-thirds of the dermis. No treatment of these

Figure 86.4 Mongolian spot of the posterior trunk.

benign lesions is necessary; however, laser can be effective for management of a persistent lesion.[35]

NEVUS OF OTA/NEVUS OF ITO

The nevus of Ota is a blue-gray facial discoloration characterized by speckled or mottled coalescing macules appearing at birth, or in childhood, in the V1/V2 distribution (Figure 86.5). Unlike Mongolian spots, these lesions do not regress and can become hyperpigmented in puberty. The lesion may extend to involve the mucosal membranes of the nose and mouth as well as sclera, conjunctiva, and retina, and ocular pathology and glaucoma have been associated. The nevus of Ota displays a female predominance and is found most commonly in Asian and Indian populations. In 10% of cases, the nevus is bilateral and associated with extensive Mongolian spots.

The nevus of Ito is a blue-gray macular lesion, similar to the nevus of Ota, that affects the shoulder area (scapula, deltoid, supraclavicular) and is sometimes associated with sensory changes. It is rarer than the nevus of Ota and more common in Asians.

Both of these lesions represent field defects of dermal melanocytosis, histologically characterized by elongated dendritic melanocytes scattered within the collagen bundles mostly in the upper third of the reticular dermis. They may contain raised areas within the lesion that are indistinguishable from blue nevus.

Although considered benign, there have been a few reported cases of malignant change, especially in areas similar to cellular blue nevus, and these may require biopsy to distinguish from melanoma.[35] Historically, cryotherapy and nonselective destruction with CO_2 laser was used with mixed aesthetic results. Current laser technology allows the surgeon to take advantage of selective photothermolysis, directing laser energy to destroy the melanocytes without damaging the surrounding tissues, with excellent cosmetic results. Multiple treatments with a Q-switched ruby laser, Q-switched alexandrite laser, or Q-switched Nd:YAG laser

(a)

(b)

Figure 86.5 Nevus of Ota/Ito. **(a)** Nevus of Ota in its typical V1/V2 distribution. **(b)** Nevus of Ito, in typical distribution involving the shoulder, neck, and back.

are effective to fade the lesion.[35] For the nevus of Ota, an ophthalmologist should be consulted due to the risk of ocular pathology.

CAFÉ AU LAIT SPOTS

Café au lait spots are benign, sharply demarcated macules of light tan to brown regular pigmentation. They can present in normal individuals or, when multiple, can be associated with syndromes such as neurofibromatosis. Histologically, lesions are caused by increased pigment in macromelanosomes within the keratinocytes in the basal layer. Laser ablation can be used to successfully treat lesions that are of cosmetic concern, but recurrence is common.[20]

NEVUS SPILUS

Nevus spilus refers to light tan to brown macules that resemble café au lait spots, but with areas of darker speckling within them (Figure 86.6). On histology, there are both areas of increased pigment within the keratinocytes of the basal layer as well as an increased number of melanocytes. The specked areas represent a mixture of findings from freckling to CMN to blue nevi. Suspicious areas within the lesion should be excised for biopsy as the nevocellular areas do carry some malignant potential. If the entire lesion is in a cosmetically sensitive area, it can be removed surgically.

SEBACEOUS NEVI

Sebaceous nevi present at birth as a waxy, hairless, yellow-orange plaque usually on the scalp, head, or neck (Figure 86.7). Over time, they can become more nodular, verrucous, and itchy, as a child approaches puberty. Sebaceous nevi are hamartomas of sebaceous glands. They carry a 15%–20% risk of malignant transformation into basal cell carcinoma, making excision and reconstruction recommended. Sebaceous nevus syndrome is the combination of large sebaceous nevi of the scalp and face associated with developmental delay, seizures, and ophthalmologic and bony abnormalities.

Extensive linear sebaceous nevus is mostly seen in the head and neck and presents some unique challenges to the reconstructive surgeon. For the larger lesions involving the scalp and face, tissue expansion can be applied in a fashion similar to that which will be described for LCMN. Narrow linear lesions can be excised in stages, often timed so a partial excision is performed at the same time a tissue expander is placed elsewhere, and further excision is done when the expander is removed for distant flap reconstruction. Lesions on the ear are addressed with either staged excision or excision and full-thickness skin graft. Those involving the helical rim should be grafted only after full growth of the ear to avoid distortion of the cartilage. It is not uncommon to see linear nevi involving the lower lip, chin, and adjacent neck. Given the linear orientation, it is important to design the reconstruction to minimize tension on the repair while breaking up the scar line to avoid scar hypertrophy and contracture. The senior author's surgical approach has been described in detail in a previous publication.[36]

Figure 86.6 Nevus spilus of the lower lip.

Figure 86.7 Extensive sebaceous nevus of the face and scalp.

SPITZ NEVI

Although not usually congenital, spitz nevi are another commonly encountered pediatric skin lesion. They present as pink, raised, firm lesions that can occasionally be pigmented (Figure 86.8). At times, they may be confused with pyogenic granulomas because of their appearance and rapid growth at onset. Originally termed *benign juvenile melanoma*, these lesions display a bizarre pathology beneath the microscope and can be confused with malignancy if the pathologist is not provided with the history of the lesion and patient's age. In fact, these lesions are benign, but do grow rapidly and tend to recur aggressively if not completely excised. Because of that, these lesions should be excised with a generous 3–4 mm border of normal tissue to decrease the chance of recurrence.

Management of CMN

The optimal management of CMN is dependent on many variables, including size and location of the lesion, malignant potential, visibility, and associated medical and psychological comorbidities. The treatment plan must therefore be tailored to the individual, with treatment

Figure 86.8 Spitz nevus.

options broadly categorized as surveillance alone, nonexcisional modalities, and excision with reconstruction.

SMALL CMN

Most CMNs fall into the small category and can usually be addressed with simple or staged excision. The low risk of melanoma before puberty in this group allows treatment to be deferred until an age at which excision can be safely performed under local anesthesia. However, if the lesion falls in a cosmetically sensitive area or is located in an area that will require general anesthesia regardless of age, consideration should be given to earlier removal to avoid potential psychological sequelae of delaying treatment. From a practical point of view, these procedures are best performed either before the patient begins toddling or just prior to school entrance in order to avoid potential complications from falls, heightened anxiety, and lack of patient cooperation found at the ages in between.

LARGE AND GIANT CONGENITAL MELANOCYTIC NEVI

Management of LCMN is a more complex, involved process that again strikes a balance between addressing the risk of malignancy and functional and aesthetic concerns, of both the lesion and subsequent reconstruction.

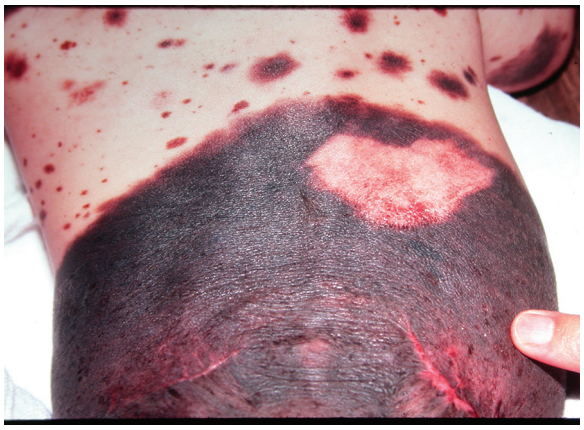
At this time, CMNs are not able to be diagnosed prenatally. The appearance of extensive dark, hairy lesions of the face, trunk, or extremities is, by nature, devastating for parents who have been anxiously awaiting the birth of their child. Because of this, the infant with LCMN should be referred early to a dermatologist and surgeon familiar with the management of these lesions. This allows parents to be appropriately counseled on the nature of these lesions, malignancy risk, and treatment options. If presented in a compassionate manner, even the news of a multiple-stage reconstruction over many years can be well accepted by families. In over 30 years of experience, the senior author has developed treatment plans for the management of these lesions with the tenet that aesthetic and functional outcome are as important as removal of the nevus itself. Although the true incidence of malignant melanoma arising in untreated LCMN is unlikely to be clearly defined, these numbers encourage early removal.

Treatment for LCMN and GCMN remains controversial to some, as they feel that the risk of malignant degeneration within these lesions is too low to warrant the extensive number of surgeries and potential scar burden associated with removal. Others feel that the potential for noncutaneous melanoma to develop in nevus cells not amenable to surgical removal (such as in NCM) represents a remaining risk that negates the effectiveness of cutaneous excision for reduction of melanoma risk.[30,37,38] However, the significant deformity and associated psychological impact caused by these lesions often tip the scales toward attempted intervention. Management plans should always strive to balance removal of the nevus with a functional and aesthetic reconstruction, and lesions that cannot be effectively addressed in this manner should be considered for conservative management by serial observation by an experienced dermatologist.

DERMABRASION, CURETTAGE, AND LASER THERAPY

Nonexcisional methods of treatment for CMN have been reported as effective methods of reducing the nevus cell burden without complete removal, improving the appearance. The success of dermabrasion and curettage relies on the finding that early in infancy, the skin nevus cells lie more superficially within the upper reticular dermis and epidermis. Dermabrasion works to abrade away these surface cells, while curettage separates the cells at the natural cleavage plane between the superficial and deep dermis. Using either method, the number of nevus cells within a lesion is reduced but not eliminated. As a result, the color of the nevus may be lightened initially but can have a tendency to darken over time (Figure 86.9a,b).[39] In addition, these treatment modalities do not show any improvement in associated hypertrichosis, due to the deeper location of the hair follicles. Finally, superficial treatment modalities are theoretically less effective at reducing malignant potential compared with excision techniques due to persistence of deeper nevus cells, and resultant scarring can potentially make follow-up examination difficult. Nonetheless, good cosmesis has been reported using both methods.[40] In order to be effective, these treatments must be performed at less than 15 days of life.

Laser offers another potential treatment strategy, attractive to both the patient and the doctor as a simpler method of reducing pigmentation without scarring. Laser therapy is well suited for the treatment of lesions characterized by superficial dermal pigmentation such as the nevi of Ota and Ito, persistent Mongolian spots, café au lait macules, and



(a)

(b)

Figure 86.9 Lightening, and subsequent repigmentation, following curettage. **(a)** The pale area within the nevus was curetted immediately after birth. Seeing this result, the rest of the lesion was curetted. **(b)** As a toddler, this typical result shows recurrence of pigmentation and scarring, making clinical and histological surveillance of the lesion difficult.

some elements of nevus spilus due to their minimal thickness, location of pigment within the dermis, and low potential for malignancy. Lasers that can be used in the treatment of CMN include ruby, Q-switched, Er:YAG, and carbon dioxide, either alone or in combination with Nd:YAG or Q-switched ruby lasers.[41] Effective treatment relies on appropriate wavelength and pulse-width selection, allowing penetration of the skin and photoselective destruction of melanin while preserving the remaining elements to avoid scarring.[35,42] Serial treatments are required, and scarring can occur with aggressive treatment or improper settings. Hypopigmentation and hyperpigmentation have also been reported, which may be temporary or permanent. Exposure to sunlight in the peritreatment period can cause significant burning, scarring, and hyperpigmentation.

Unfortunately, because CMN display nevus cells within all layers of the skin as well as within the deeper structures, it is unrealistic to think that a laser could effectively penetrate to the depths necessary to eliminate all pigment-producing nevi cells without significant secondary damage and scarring. In addition, laser treatment vaporizes the specimen, therefore eliminating histologic evaluation of the lesion to determine its nature. Finally, the impact of the exposure of nevus cells to sublethal doses of laser energy associated with laser therapy is unknown, and may not be apparent for many years into the future.[43,44]

Although dermabrasion, curettage, and laser offer relatively simple approaches to improving the appearance of CMN, they present many drawbacks. Leaving residual nevus cells within CMN imparts a continued risk of malignancy, and scarring may make monitoring the lesions more difficult posttreatment. In addition, scarring from these therapies may complicate ultimate excisional treatment options in the future. Finally, the delay of more definitive reconstruction may have its own psychological effects on a child. Although limited use of these therapies may be useful in certain areas of reconstruction (such as lightening of a thin lesion in the cosmetic and functionally sensitive eyelid area), thoughtful consideration is warranted prior to widespread implementation of these modalities in a treatment algorithm for LCMN.

SURGICAL EXCISION AND RECONSTRUCTION

The benefits of surgical excision of LCMN include complete removal of nevus cells in the involved skin and subcutaneous tissue. Although some have focused on reconstruction with skin grafts, skin substitutes, or cultured epithelium, whenever possible, the use of tissue expansion allows the most functional and aesthetic result by allowing replacement with full-thickness normal tissue. Excision of the nevus is usually carried out at the level of the deep fascia.

Goals of treatment include complete excision at an early age, minimization of scarring, and functional impact, with a low requirement for future procedures. Early excision is emphasized for four reasons. First, the greatest risk for malignancy is reported in childhood, most notably in the first 3 years of life. Second, the elasticity and healing capacity of the skin is better the younger the patient. Third, patients operated on in infancy tolerate surgery better both physically and emotionally than their older counterparts. Finally, by completing reconstruction early, the psychological impact of the lesions and surgical interventions can be reduced.

In 1988, the senior author presented a coordinated approach to the management of these lesions in 78 patients.[45] This report outlined the spectrum of treatment options

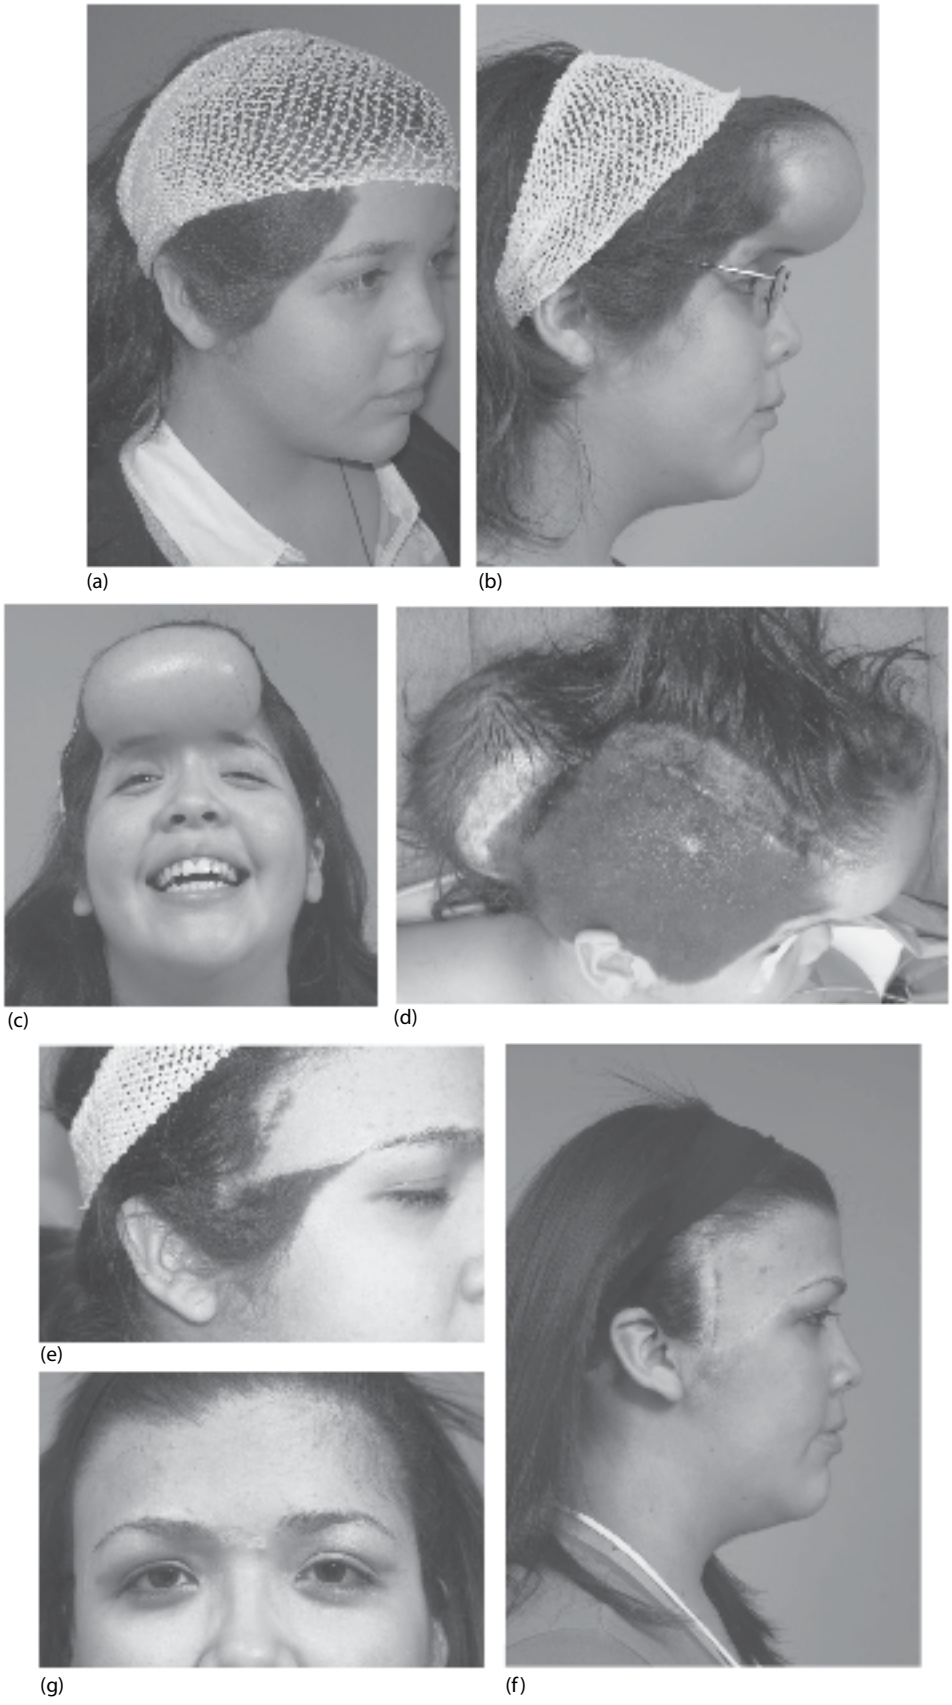


Figure 86.10 **(a)** Large CMN of scalp and forehead. **(b, c)** Lateral and frontal view after completion of forehead expansion. **(d)** At surgery with views of both forehead and occipital scalp expanders, 12 weeks after expander placement. **(e)** Result after first stage. **(f, g)** Final reconstruction of aesthetic units with scars well concealed at hairline and along the browline.

from skin graft to tissue expansion, and assessed the effectiveness of excision and reconstruction with each technique in each body region. Since then, further experience with over 300 patients has allowed further development and refinement of this approach.[46–50] Although a full discussion of the nuances of management of each type of LCMN is beyond the scope of this chapter, the following is a summary of the author's current approach.

Scalp

Scalp reconstruction is complicated by its relatively inflexible quality and the unique aesthetics of maintaining hair quality and direction. Because of this, tissue expansion remains the workhorse for scalp reconstruction following excision of LCMN. Scalp lesions are best reconstructed in stages, with placement of one or more tissue expanders in the subgaleal plane beneath adjacent normal scalp skin. Following a period of 10–12 weeks of expansion, the expanders are removed, lesions excised, and the defect closed using both advancement and transposition flaps designed to preserve hair direction and hairline.[46] Serial expansions are often necessary, and flaps should be carried out and their viability assessed before nevus excision (Figure 86.10). Safe expansion of the infant scalp can be carried out at 6 months of age, with careful attention given to the fontanel during expander placement and reconstruction. Although temporary cranial molding is common, in the authors' experience, no infants have demonstrated permanent skull deformities. Spontaneous contour correction generally occurs within 3–4 months following expander removal.

Face

LCMNs of the face present some of the greatest reconstructive challenges. By dividing the face into aesthetic units and placing expanders under adjacent normal skin in the neck and forehead, skin of excellent quality match can be used while allowing scars to lie less conspicuously at the junction of aesthetic units (Figure 86.11). When advancing tissue from the neck into the cheek area, a transposition design can help improve flap movement while aligning the scars optimally. Whether the flap is based laterally (most common) or medially, the transposition minimizes the risk of late downward drift of the flap and ectropion of the lower eyelid.[46] Lesions of the nose are best resurfaced with an expanded forehead flap carried on a superficial temporal artery pedicle when available, or with an expanded supraclavicular full-thickness skin graft. The periorbital area is also best addressed with expanded full-thickness skin grafts to allow preservation of the thin nature of the tissue while decreasing incidence of ectropion.[48] LCMN of up to 75% of the forehead can be managed with tissue expansion, often serial, and this requires careful planning to minimize distortion of the eyebrow position and maintain the normal distance from brow to hairline. Nevi extending into the temporal area must be treated by expansion of both scalp and forehead, with flaps designed to establish both normal position of the hairline and hair direction for the temporal scalp.[50]

There was some later darkening pigmentation outside the margins of the original resection, best seen along the nasal sidewall.

Trunk

The frequently extensive involvement of GCMN of the trunk with relative lack of normal donor skin presents a daunting challenge to the reconstructive surgeon, leading many to resort to split-thickness skin graft–based reconstruction. The inferior functional and aesthetic results of this approach call into question whether excision should have been undertaken at all, in favor of conservative observation. With improved expanded flap design carried out in series, or the use of expanded distant flaps with microvascular transfer, superior trunk reconstruction can be achieved.

The posterior trunk is the most common location of GCMN, often extending anteriorly in a dermatomal distribution. These lesions, including the "bathing trunk" distribution and large thoracic nevi, are best reconstructed with serial tissue expansion and subsequent transposition flap closure (Figure 86.12). Anterior trunk lesions can be

treated with an abdominoplasty technique, with or without expansion depending on lesion size. When adjacent donor sites are unavailable for expansion, excision and reconstruction of shoulder, upper back, and posterior neck nevi can be accomplished using microvascular transfer of a free expanded transverse rectus abdominis musculocutaneous (TRAM) or deep inferior epigastric perforator (DIEP) flap (Figure 86.13). With increased use of expanded flaps over skin grafting for trunk reconstruction, late contour deformities seen at junction points between grafted and ungrafted areas can be significantly reduced. These modified techniques can result in aesthetic benefits far beyond what may be accomplished with alternative treatments.

Extremities

LCMNs of the extremities continue to present a considerable challenge, due to the limitations of local expansion techniques in these areas and the relatively poor aesthetic outcome seen with skin grafting. The authors' prior approach utilized both split-thickness and expanded full-thickness skin grafts for most lesions, but long-term soft-tissue contour defects and pigment abnormalities in the grafted skin have led to use of alternative approaches whenever possible. In upper extremity lesions, transposition flaps from the upper back and shoulder have effectively eliminated contour defects to the proximal upper extremity. In addition, three-stage, expanded pedicled flaps from the abdomen and flank can be designed to provide complete coverage of a circumferential nevus from elbow to wrist, with excellent contour and acceptable scarring achieved at both donor and recipient sites (Figure 86.14).[49] A similar pedicled approach has been successful in providing coverage for lower leg lesions after ipsilateral thigh expansion in the young infant, when lower extremity flexibility is at its peak, with excellent results.[49] Finally, expanded free flaps offer another alternative for coverage of larger lesions of the extremities, with excellent functional and aesthetic results.

Complications

Complications of surgical excision of LCMN with expanded flap reconstruction are uncommon, despite the complex nature of these procedures. They include expander infection/exposure, partial flap necrosis, wound dehiscence, and scarring. The incidence of expander infection has been reported at 5%, which can be due to inoculation at the time of placement or during the expansion process, or by hematogenous seeding from a distant infection.[51] These infections can usually be managed conservatively with systemic antibiotics, allowing completion of expansion and successful reconstruction. A low threshold for placement on oral antibiotics during healing problems or systemic illness occurring during expansion may help minimize risk.

The expansion process effectively increases vascularity of the overlying flap through the delay phenomenon,[52] making flap ischemia rare. Preservation of the capsule and avoidance of excessive tension during closure can prevent this potentially devastating complication. Finally, meticulous closure and postoperative scar management help achieve optimal results.

CONCLUSIONS

The treatment of congenital large and giant nevi presents a continuing challenge to all individuals involved with these patients. The ability to present an organized discussion of current views on risk of malignant change to parents, older patients, referring physicians, and other allied health care workers is critical. Treatment strategies should take into consideration the varied opinions regarding malignant risk, emphasize the benefits of early excision on lowering that risk, and most importantly, provide a means of dealing with these often devastating lesions in a manner that optimizes the functional and aesthetic outcome, minimizing the need for major reconstruction in later life.

Lymphatic malformations

EMILY R. CHRISTISON-LAGAY AND JACOB C. LANGER

INTRODUCTION

Lymphatic malformations (LMs) constitute one subset of a larger group of so-called vascular malformations, which may affect any segment of the vascular tree, including arterial, venous, capillary, and lymphatic vessels. All vascular malformations can be considered to be the result of errors of embryonic development and can be categorized according to the particular vascular component involved as well as by physiologic flow properties. Thus, there exist slow-flow lesions (which include lymphatic, venous, and capillary malformations); fast-flow anomalies (which contain an arterial component); and complex, combined vascular malformations.

Commonly referred to as "cystic hygroma" or "lymphangioma" in the historic literature, LMs consist of a group of developmental anomalies of the lymphatic system. They are slow-flow anomalies, which range in clinical presentation from small masses to large and sometimes debilitating, disfiguring, or invasive lesions. Structurally, they may be characterized as *microcystic*, *macrocystic*, or combined lesions, and these properties have significant clinical implications for treatment. The most common presentation of a macroscopic LM is a ballottable mass beneath normal skin, although a large LM may transilluminate, causing the overlying skin to attain a blue hue. Microcystic malformations may present as vesicles that permeate the subcutaneous tissue and muscle. Dermal lymphatic involvement causes puckering, dimpling, vesiculation, or even brawny edema.[1] Approximately 40%–50% of LMs are found in the neck and shoulder; however, they may also occur in the mediastinum, retroperitoneum, groin, and other lymphatic-rich regions. Histologically, LMs are comprised of vascular spaces with a single layer of flattened epithelial cells. This chapter will provide an overview of the diagnosis and management of these often difficult lesions with emphasis on those involving the head and neck region.

EMBRYOLOGY AND ETIOLOGY

Most LMs are sporadic, but some exhibit classic Mendelian inheritance. Although our understanding of lymphatic development (and by extension, errors in lymphatic development) is less comprehensive than that of venoarterial development, recent advancements in distinguishing early lymphatic endothelial cells (LECs) from blood endothelial cells have opened the door for greater insight into observed aberrancies.

Seminal observations by Sabin[2] in the early twentieth century described the development of the lymphatic system beginning in the sixth to seventh week of embryonic life, approximately 4 weeks after the onset of vasculogenesis with the formation of five primitive "lymph sacs" originating as a set of paired sacs lateral to the jugular vein, a retroperitoneal sac at the root of the small bowel mesentery, and paired sacs posterior to the sciatic veins. It took nearly a century of investigation before this process was understood in more detail.

Migration of a specialized subset of endothelial cells from the anterior cardinal vein occurs in response to the stepwise expression of a series of transcription factors including Sox19, COUP-TPII, and Prox1.[3–5] Prox1 is considered to be a "global regulator" of lymphatic development required not only for lymphangiogenesis but also for maintenance of a lymphatic phenotype postnatally. The expression of the specific lymphatic receptor vascular endothelial growth factor receptor 3 (VEGFR3) permits separation (or budding) of the lymphatic system from the venous system.[5–8] Once the fate of LECs has been specified, migrating cells are able to respond to peripheral gradients of VEGF-C. LEC migration is a complex process that appears to depend upon relative levels of neuropilin2 and lymphatic vessel endothelial hyaluronan receptor 1 (LYVE-1). Those LECs expressing high neuropilin2 and low LYVE-1 migrate away from their precursor vein and form superficial lymphatic arbors. Conversely, those LECs expressing low levels of neuropilin2

and high LYVE-1 form a balloon-like structure adjacent to their precursor vein, eventually giving rise to larger lymphatic channels.[9,10] Complete separation of venolymphatic structures is also dependent upon the formation and signaling of platelet microthrombi. If this does not occur, the lymphatic channels end up filled with blood.[11]

Ongoing remodeling, proliferation, and maturation of LECs with lymphatic sprouting and valve development are subject to an extraordinarily precise choreography of growth factors and signaling molecules. Important regulators include VEGF and the VEGF receptor families, ephrins, angiopoietins and the Tie-2 receptor, transforming growth factor-beta (TGF-β) and its receptor, platelet-derived growth factor subunit B (PDGF-B) and its receptor, the Notch and Jagged families of membrane-associated molecules and the integrin family of cell surface receptors.[12–14]

Overexpression of the isoforms VEGF-C and VEGF-D in transgenic mice induces the formation of hyperplastic lymphatic vessels.[6] Kinase-inactivating mutations in the human *VEGFR3* gene result in Milroy disease.[15–17] Mutations in Sox18 are associated with hypotrichosis–lymphedema–telangiectasia.[9] Tie-2-deficient mouse embryos demonstrate normal initial vasculogenesis but have a disorganized vascular network lacking appropriate hierarchical organization.[18] Tie-1-deficient models demonstrate decreased endothelial cell integration leading to embryonic edema, hemorrhage, and death, and the Tie-1 receptor has recently been shown to be required for normal embryonic lymphangiogenesis.[19,20] Ang1–4, members of the angiopoietin family, likely have roles in vessel stabilization and lymphatic development.[21] Mutations in the *Fox* family of transcription factors have been associated with congenital lymphedema, and this family is thought to play a role in the formation of lymphatic valves.[22,23] Mutations or deletions in specific integrin subtypes can lead to abnormal lymphatic development.[24] Recently, integrin-α9 was found to be necessary for normal lymphatic valve morphogenesis and may be implicated as a candidate gene for primary lymphedema caused by valve defects.[25–27]

PRENATAL DIAGNOSIS

LMs are often diagnosed by prenatal ultrasound in the late first trimester.[28] The differential diagnosis of a cystic lesion in the fetus is extensive, but in experienced hands, the correct diagnosis can be made in most cases.[29] Although most LMs presenting to the pediatric surgeon have an excellent prognosis, prenatal sonography has revealed a high "hidden mortality" among fetuses with this condition.[30] Many fetuses with an LM develop hydrops fetalis or diffuse lymphangiomatosis prior to fetal demise (Figure 87.1). There is often either an associated chromosomal abnormality (e.g., Turner syndrome) or a familial syndrome associated with other structural anomalies (e.g., multiple pterygium syndrome, Robert syndrome).[31,32] Although most of these fetuses die in utero, spontaneous regression has occasionally been observed.[33–35] The natural history of cervical lesions detected prenatally varies according to the gestational age at which nuchal thickening appears and is further influenced by the presence or absence of hydrops or abnormal karyotyping. The cases diagnosed in the first trimester without any karyotypic abnormality usually have good prognosis with spontaneous resolution in the majority.[36–39] Conversely, those with hydrops and abnormal karyotype have a poorer outlook.[40,41] The prognosis of patients detected in the second trimester is usually poor.[42] LMs diagnosed in late gestation appear to belong to a different spectrum of disease with a much more favorable prognosis. These cases are comparatively rare and likely to represent an etiologic mechanism occurring during the latter half of pregnancy. Prenatal diagnosis should be followed by delivery and aggressive surgical management at a perinatal center.[43,44]

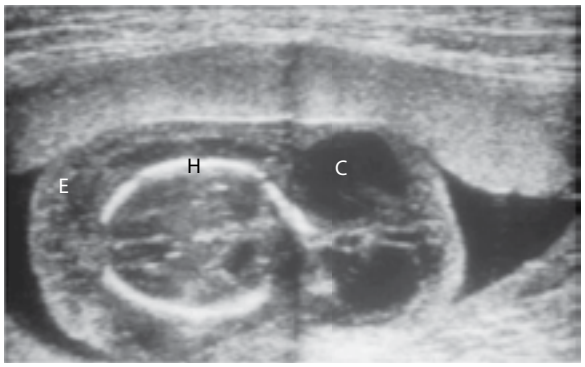

Figure 87.1 Prenatal ultrasound of a fetus with Turner syndrome and a large posterior cervical cystic hygroma. Note the diffuse subcutaneous edema (E), which is indicative of hydrops fetalis. H = fetal head, C = cystic hygroma.

Occasionally, a fetus may be identified with a large anterior cervical LM that causes airway obstruction. These pose a challenge at the time of delivery and are best managed using the ex utero intrapartum (EXIT) procedure to gain access to the airway prior to dividing the umbilical cord (Figure 87.2).[45–47] In severe cases, a tracheostomy can be done, or the child can be placed on extracorporeal membrane oxygenation as part of the EXIT procedure; however, most patients with even large cervicofacial LMs can be orotracheally intubated in the delivery room.

Those LMs that are not diagnosed prenatally are generally evident at birth or before age 2 years; however, occasionally, they can manifest suddenly in older children and adults due to intralesional bleeding or infection.

CLINICAL PRESENTATION AND IMAGING

The majority of LMs occur in the head and neck, axilla, or retroperitoneum; involvement of the mediastinum, groin, extremities, or face is less common. Approximately 80% are diagnosed before the age of 5 years, and over half are present in the newborn period. Unlike infantile hemangiomas, LMs do not involute but grow proportionally with the growth of the child. LMs of the neck typically contain

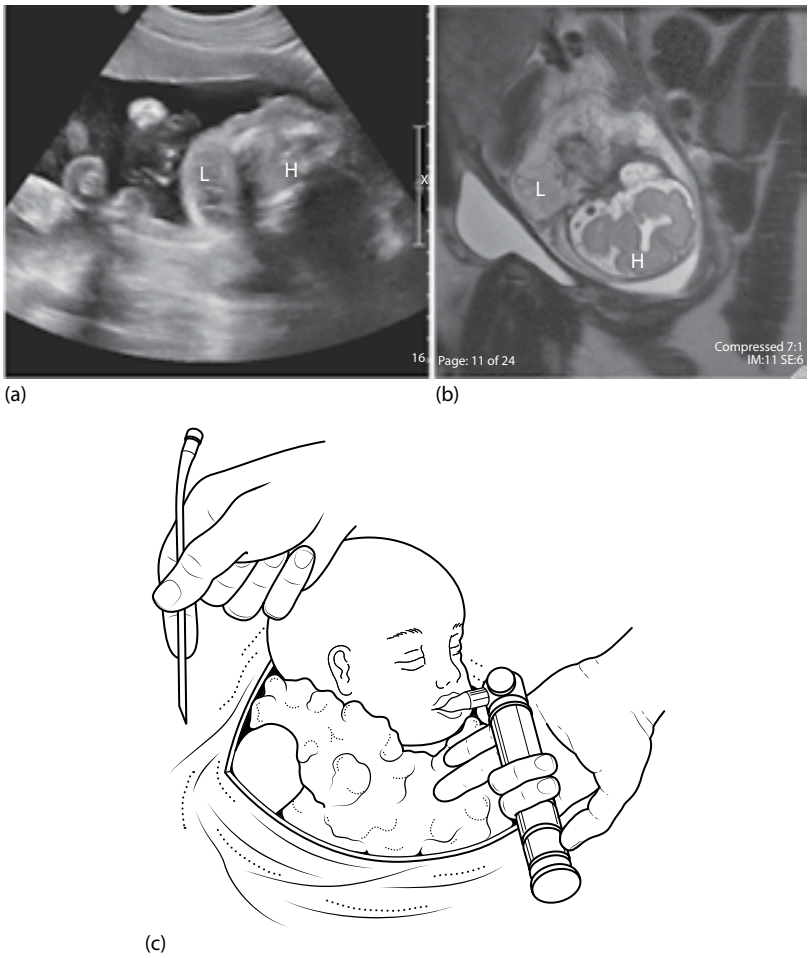

Figure 87.2 **(a)** Prenatal sonogram and **(b)** MRI showing a large pretracheal lymphatic malformation. H = fetal head, T = lymphatic malformation. **(c)** The EXIT procedure, in which intubation is accomplished prior to delivery while still on placental support.

a large macrocystic component and present as a soft, fluctuant swelling in the lateral or anterior neck. These lesions are frequently asymptomatic, and age-related growth is variable (Figure 87.3). While classically referred to as "cystic hygroma," this term is discouraged in contemporary literature as the suffix *-oma* suggests a neoplasm (which it is not) and, furthermore, the term is frequently used in the obstetrical literature to describe a posterior cervical cyst with associated lethal chromosomal abnormalities.[48] The approach to LMs depends upon anatomic location and degree of involvement of vital structures and will be discussed in greater detail in this chapter.

Figure 87.3 Five-month-old child with moderate-sized lymphatic malformation, which was relatively asymptomatic.

Head and neck

A staging system for LMs of the head and neck was proposed by de Serres et al.[49] (Table 87.1) based upon the anatomic

Table 87.1 De serres staging of cervicofacial lymphatic malformations

Stage	Anatomic Location
I	Unilateral infrahyoid
II	Unilateral suprahyoid
III	Unilateral infrahyoid and suprahyoid
IV	Bilateral infrahyoid
V	Bilateral infrahyoid and suprahyoid

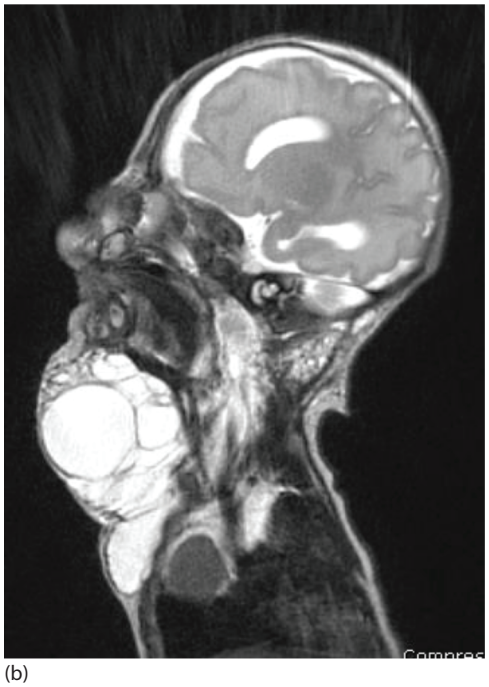
location of the malformation. Increasing stage is correlated with increasing complexity of treatment approach, increasing complication rate, and increasing number of necessary therapeutic interventions. Since that initial description, there have been multiple refinements based upon extent of oral and pharyngeal involvement. Lesions involving the tongue are only appropriate for complete resection with organ preservation if the tongue is involved partially or superficially.

LMs in the forehead and orbit are frequently combined macrocystic and microcystic lesions and may diffusely infiltrate the intraconal and extraconal space, causing localized overgrowth and proptosis, which makes surgical excision difficult (Figure 87.4). Cervicofacial malformations can be associated with mandibular overgrowth, causing an underbite.[50] LMs in the floor of the mouth and tongue are characterized by vesicles, intermittent swelling, and bleeding. Occasionally, huge malformations involving the floor of the mouth or the larynx will present at birth with airway obstruction. Rapid increases in size or sudden pain may be due to hemorrhage into the tumor, or to infection. Cervical malformations involving the supraglottic airway may necessitate tracheostomy.

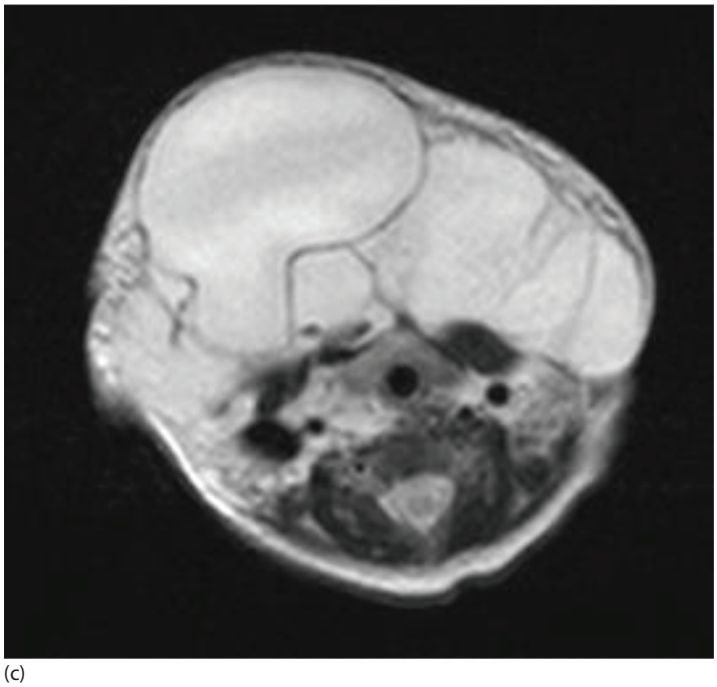
Trunk and extremities

Diffuse thoracic lymphatic anomalies or rare abnormalities of the thoracic duct or cisterna chyli can manifest as

(a)



(b)



(c)

Figure 87.4 **(a)** Newborn with large lymphatic malformation. **(b)** Sagittal T2-weighted MRI demonstrating combined microcystic–macrocystic lesion. **(c)** Axial section of MRI

recurrent pleural and pericardial chylous effusion or chylous ascites. Anomalous lymphatics in the gastrointestinal (GI) tract can cause chylous ascites or present with a (typically asymptomatic) cystic abdominal mass (Figure 87.5). Both congenital chylous ascites and chylothorax may be associated with the development of hypoalbuminemia as the result of chronic protein-losing enteropathy. LMs of the extremities may be small and localized or may involve the entire extremity in an infiltrative and debilitating fashion associated with both soft tissue and skeletal overgrowth. Pelvic malformations can be accompanied by bladder outlet obstruction, constipation, or recurrent infection.

Syndromes associated with LMs

Occasionally, LMs occur in the constellation of a well-described phenotype. The eponym *Gorham–Stout syndrome* has been applied to a phenomenon involving progressive osteolysis, caused by diffuse soft tissue and skeletal LMs. Alternative names include "disappearing bone disease" or "phantom bone disease."[51] *Klippel–Trenaunay syndrome* is a well-described combined capillary–lymphatic–venous malformation associated with soft tissue and skeletal hypertrophy. The capillary malformations are multiple and typically arranged in a geographic pattern over the lateral side of the extremity, buttock, and/or thorax. Lymphatic hypoplasia is present in greater than 50% of patients with associated lymphedema or isolated lymphatic microcysts. *Parkes Weber syndrome* shares many similarities with Klippel-Trenaunay syndrome but should be distinguished by a component of an additional capillary–arteriovenous malformation. Lymphedema should also be included as a type of LM. Type I hereditary lymphedema (*Milroy disease*) is an autosomal dominant disorder presenting early in life with localized areas of edema. Affected areas are characterized by absent or hypoplastic superficial lymphatics. Type II hereditary lymphedema (*Meige disease*) is a late-onset autosomal dominant disorder attributed to a mutation in the FOXC2 gene with variable penetrance and phenotype. Associated features include distichiasis (a double row of eyelashes), ptosis, cleft palate, yellow nails, and congenital heart disease.[23] The disorder is thought to arise from an impairment of lymphatic drainage, and lymphoscintigraphy demonstrates numerous dilated lymphatic vessels.

RADIOGRAPHIC INVESTIGATIONS

Magnetic resonance imaging (MRI) is the most useful imaging modality for LMs, aiding in the classification of macrocystic and microcystic lesions as well as defining anatomic relationships, including important neurovascular structures (e.g., brachial plexus and carotid artery).[52–55] LMs demonstrate hyperintense signal intensity in T2-weighted and turbo-Short TI Inversion Recovery (STIR) images as well as rim enhancement after contrast application. Microcystic lesions have an intermediate signal in T1 sequences and an intermediate to high signal on T2 sequences. Macrocystic lesions show low intensity in T1 and high intensity in T2. The new generation of ultrafast MRI scanners has permitted this technique to be used more frequently in small infants, and even in affected fetuses.[56,57]

Ultrasound may be a helpful adjunct in confirming the presence of macrocystic LMs, and Doppler studies may be of additional assistance in looking at flow properties.[58] Computerized tomography (CT) is extremely useful for assessing relationships to adjacent structures, especially within the mediastinum and retroperitoneum.[56,59,60]

Conventional contrast lymphangiography is rarely performed but may be of help in establishing the location of a lymphatic or chylous leak in a patient with a diffuse thoracic lymphatic anomaly.[61] Boxen et al.[62] described the use of lymphoscintigraphy to define the lymphatic supply of a large LM.

Often, a combination of techniques must be used to completely define the anatomic relationships of a large or complicated lesion.

DIFFERENTIAL DIAGNOSIS

The diagnosis of LM is usually straightforward and can be easily differentiated from lymphadenopathy, teratomas, and other solid tumors based on the clinical examination and imaging studies. Lipomas may also be confused with superficial LMs but will not have a cystic appearance on ultrasound examination. Hemangiomas may be present in the same location, but do not transilluminate and tend to collapse on compression. However, there are some patients who have features of both lymphatic and vascular malformation within the same lesion.

COMPLICATIONS

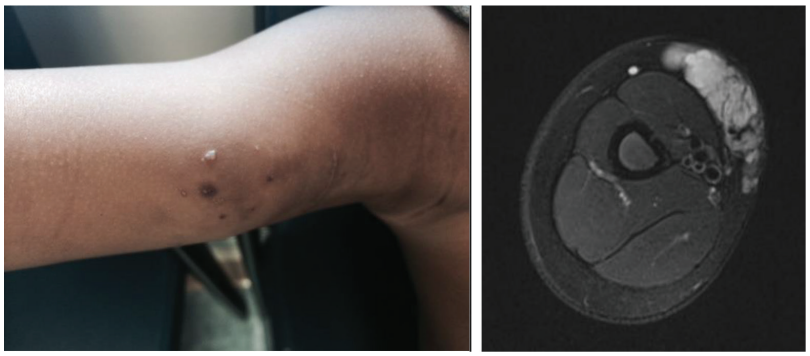
The two principal complications of LMs are intralesional bleeding and infection. Bleeding may occur spontaneously or as a consequence of trauma. It is associated with rapid, painful enlargement of the lesion with attendant ecchymosis. Analgesia and observation are generally sufficient treatment. Prophylactic antibiotics are recommended in the setting of a large bleed. Hemorrhage and infection can transform a macrocystic lesion into a microcystic and scarred lesion.

It is not uncommon for LMs to increase in size in the event of a viral or bacterial infection. This is typically self-limited and thought to be related to changes in lymphatic flow. Nonetheless, bacterial superinfection of the malformation can cause an ascending cellulitis and septicemia, and can be fatal. Additionally, an infection in a cervicofacial LM can cause obstruction of the upper airway and dysphagia. Prolonged intravenous antibiotic therapy is frequently indicated, with choice of broad-spectrum antibiotic agents directed against oral pathogens in the head and neck or enteric organisms in the trunk or perineum.

MANAGEMENT

The two principal modern strategies for treating lymphatic anomalies are sclerotherapy and surgical resection. Historically, irradiation, incision and drainage, and thermosclerosis or irritant sclerosis have all been advocated as nonsurgical treatments.[63,64] With the exception of sclerotherapy, none have demonstrated reproducible success. Sclerotherapy uses a variety of agents to induce obliteration of the lymphatic lumen by chemical destruction of the endothelium with subsequent sclerosis/fibrosis. Success parallels the degree of damage inflicted upon the endothelial and deeper muscular and connective tissue layers. In general, macrocystic LMs are more amenable to sclerotherapy than microcystic lesions because it is possible to drain the entirety of the cyst cavity and induce endothelial apposition prior to administration of a sclerosant. A number of sclerosing agents have been described including doxycycline, OK-432 (Picibanil), ethanol, sodium tetradecyl sulfate (STS), and bleomycin.[65–77] A recent meta-analysis of five retrospective series of children with macrocystic or mixed lesions of the head and neck treated with doxycycline (at a preferred concentration of 10 mg/mL) found 84.2% to be successfully treated, with 20% of those requiring only a single session.[67] Doxycycline is generally well tolerated with minimal side effects. The most commonly reported adverse reactions were cyst hemorrhage, cellulitis, pain, and transient edema. Less commonly, scarring, skin excoriation, and Horner syndrome were reported. These side effects are likely to be related to the sclerosant effect of doxycycline rather than a side effect of the medication itself and are typically self-limited.[78] OK-432, a bacterial product derived from *Streptococcus pyogenes*, induces a significant local inflammatory response and has reported durable success rates (good or excellent results) in 60%–100% of patients.[71,74] The mechanism of action of OK-432 is not completely understood but likely reflects a multitiered activation of the immunologic system including neutrophils, macrophages, natural killer (NK) cells, and T-cells.[72] Despite good success rates and infrequently reported complications, OK-432 is not available in North America but is often a first-line treatment in Europe and Japan.

Recently, several authors have supported the use of bleomycin sclerotherapy (at a concentration of 1 U/mL) in microcystic LMs. The mechanism of action that allows it to be more effective than other sclerosants on microcystic disease is not completely understood but may involve either disruption of tight junctions or induction of endothelial



(a) (b)

mesenchymal transitsion.[75] The majority of patients exhibit either a complete (approximately 30%–40%) or partial (50%–60%) response.[75,77] Concerns about bleomycin-induced pulmonary fibrosis have not been substantiated.

Until recently, there were only anecdotal reports of medical management successfully being used as treatment for unresectable LM with no agent demonstrating consistent efficacy. Over the last several years, however, there has been considerable interest in the novel emerging role of several medications including sildenafil and propranolol. Perhaps the most excitement has been generated by sirolimus, an mTOR inhibitor, which blocks the phosphoinositide3-kinase (PI3K)/acutely transforming retrovirus (AKT) pathway of VEGF activation. A recently published Phase II study reported that 100% of patients demonstrated a partial response of large, otherwise unresectable microcystic LM to a 12-week course of sirolimus.[79] Sirolimus has also demonstrated efficacy in kaposiform lymphangiomatosis and lymphangioleiomyomatosis.[79,80]

Although safe surgical excision is possible in most small LMs, some reports in the past decade have advocated injection sclerotherapy for cases that are located in regions where resection would be too hazardous, for cases that have been incompletely resected, and for recurrent disease. Many studies suggest that in such cases, sclerotherapy and surgical therapy have similar results and the treatment selected should reflect upon the strengths and experience of the treating team.[81,82] No carefully controlled study comparing the efficacy of sclerotherapy to surgery has ever been reported. Most articles describing surgical treatment use it as the primary treatment modality, whereas sclerotherapy is described as primary therapy in most cases (approximately 70%) but as secondary therapy following surgical resection in 25%.[82] The successful surgical management of complex (often mixed or microcystic) LM is often staged. In each resection, a surgeon should focus on a defined anatomic region, attempt to limit blood loss, perform as thorough a dissection as possible and be prepared to operate as long as necessary. Even with such an intensive approach to resection, subsequent "recurrence" is as high as 40% after an incomplete excision and 17% after a macroscopically complete excision.[83] In some patients, persistent disease at the margins can recur as vesicles along the suture line, so-called lymphangioma circumscriptum (Figure 87.6). Multiple methods have been described to treat lymphangioma circumscriptum including surgical excision, lasers, sclerotherapy, electrocoagulation therapy, and topical sirolimus.

SURGICAL MANAGEMENT

Many LMs can be resected without undue morbidity. Although pathological studies have shown that microscopic tumor is often left behind, recurrence is rare when all gross tumor is removed.[83] The following surgical principles must guide resection:

1. Adequate exposure must be obtained.
2. Meticulous dissection must be used in order to preserve vital structures, including nerves, vessels, trachea, and esophagus. We have had success with the use of a microbipolar dissection technique. This technique is of particular advantage when dissecting close to important neurovascular structures.
3. Since this is a benign disease, it is not justifiable to sacrifice a vital structure in order to completely excise the lesion.
4. Whenever possible, the lymphatic supply to the lesion should be ligated to prevent postoperative accumulation of lymph. In the head and neck region, the lymphatic supply to an LM is usually not visible, but it is possible that the microbipolar dissection technique may "weld" these channels shut.

LMs of the neck can usually be approached through a transverse cervical incision under general intratracheal anesthesia. Perioperative antibiotics should be employed. After division of the platysma muscle, the mass is carefully dissected from all surrounding structures (Figure 87.7). Large cystic malformations are usually well encapsulated, and every attempt should be made not to rupture the cysts. The fluid within the cyst aids the surgeon in defining the

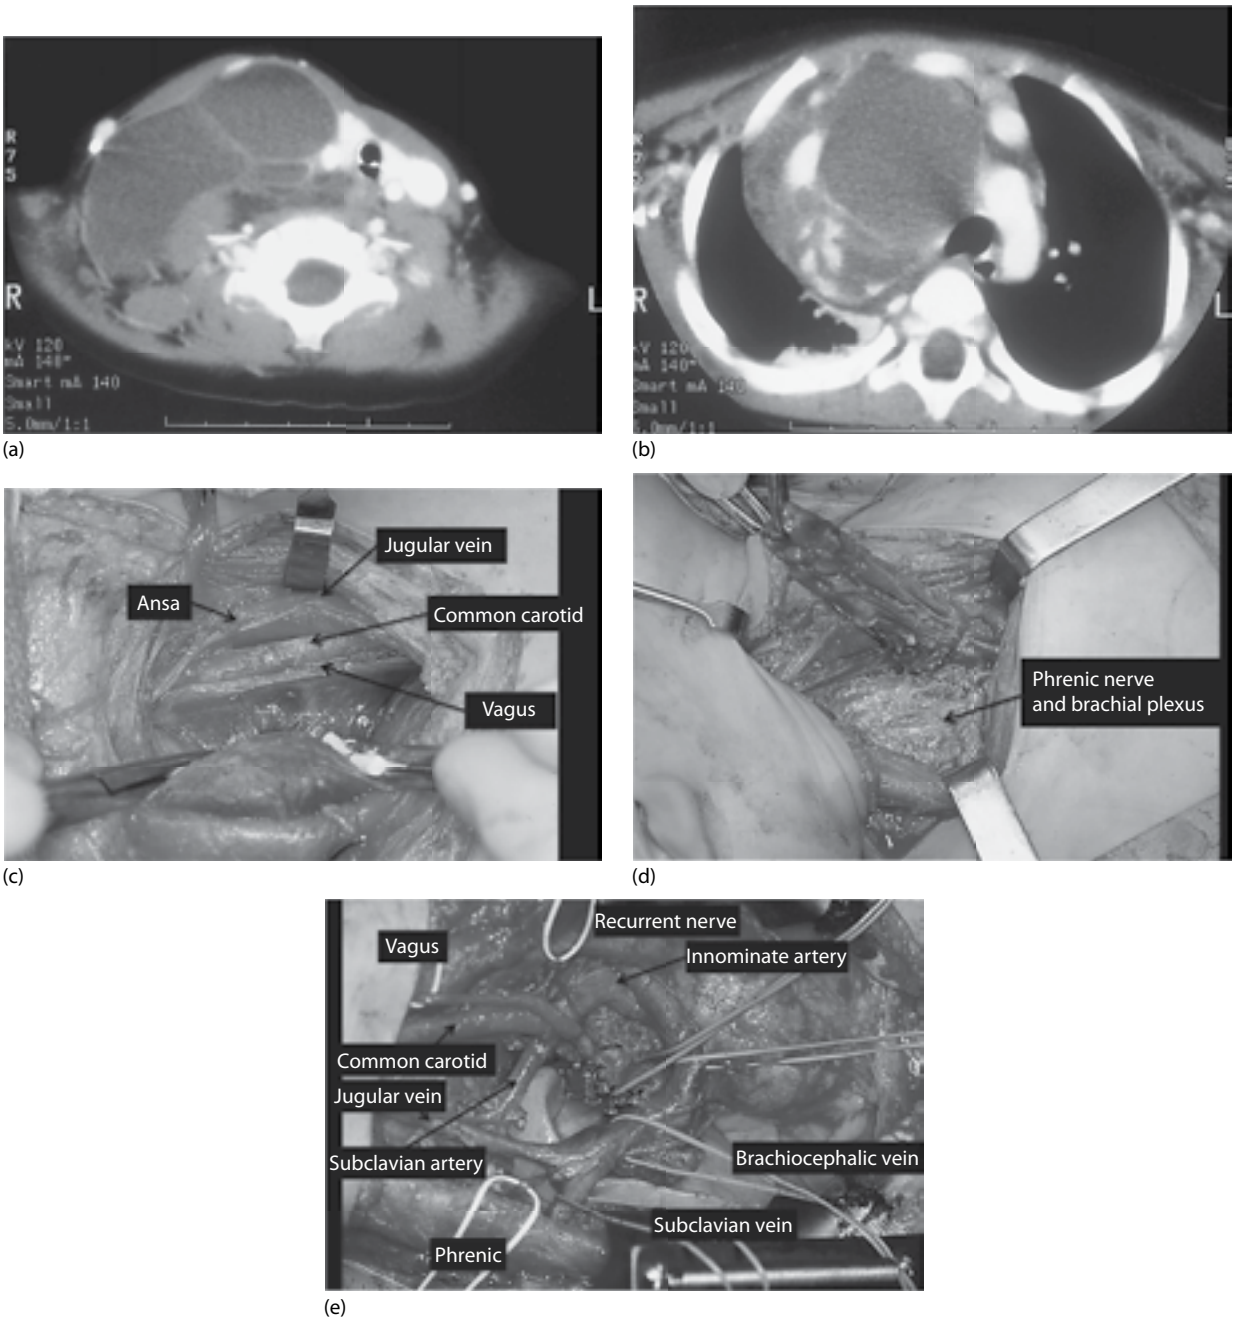

Figure 87.7 Surgical exposure of a cervicomediastinal lymphatic malformation. Note location of vital neurovascular structures, which must not be damaged during the dissection. **(a** and **b)** CT scan demonstrating the lesion. **(c** and **d)** Dissection of the cervical portion. **(e)** Completed mediastinal dissection after extension of the incision and sternotomy. (Courtesy of Dr. Vito Forte.)

cyst wall, and therefore in finding the correct plane in which to dissect. Particular care must be taken to avoid injury to the carotid artery and its branches, or to the internal jugular vein. Preservation of other large venous channels, if possible, may also be beneficial in promoting regional drainage. A number of nerves are often closely associated with the lesion, including the facial nerve, the spinal accessory nerve, the vagus nerve, and the brachial plexus. Once the malformation has been removed, and, if possible, the lymphatic supply to the malformation ligated, a closed-suction drain should be left in the tumor bed to prevent early accumulation of fluid. Dietary restriction of long-chain triglycerides in the postoperative period may be of some benefit in reducing the amount of chylous lymph production.

A small number of cervical lesions extend into the axilla or the mediastinum. For axillary extension, the child should be elevated 15–20 degrees on the involved side, with the arm draped free, and both cervical and axillary crease incisions should be used. The cervical component is approached first,

separating the lesion away from the brachial plexus until the cysts are seen to pass below the clavicle. The axillary portion is then dissected free. The most difficult aspect of the operation is removing the lesion from the brachial plexus behind the clavicle, where it is often densely adherent. Only careful, meticulous dissection will permit complete removal of the malformation without injury to the nerves.

Extension into the mediastinum also presents a difficult technical challenge. The best approach is one-stage resection through an "inverted hockey-stick" incision, as described by Grosfeld, whereby a transverse neck incision is extended inferiorly into a midline sternotomy.[84] Modifications of the Grosfeld approach, either by leaving a bridge of skin between the horizontal cervical and midline sternotomy incisions or by performing a partial upper sternotomy through the cervical incision, may provide a cosmetically superior result without significantly compromising exposure. These approaches provide adequate exposure to safely dissect the lesion away from the jugular, carotid, and subclavian vessels, and the aortic arch, esophagus, and pericardium, with preservation of the phrenic, vagus, and recurrent laryngeal nerves. The rare LM that is confined to the mediastinum can be approached through a lateral thoracotomy, a midline sternotomy, or a thoracoscopic approach.

Perhaps the most difficult lesions to approach surgically are the massive lesions that involve the tongue, floor of the mouth, and larynx. These lesions are usually present at birth and may result in early airway obstruction, either by sheer mass effect or as a result of hemorrhage into the tumor. In many cases, a tracheostomy is necessary, followed by multiple extensive operative procedures. Additionally, placement of a gastrostomy tube should be considered for any patient with a large cervical facial LM requiring multiple operative procedures and who may have oropharyngeal discoordination. For such lesions, combined treatment modalities including sclerotherapy (for macrocystic components), systemic therapy (sirolimus), and surgery may offer the best outcome. For prenatally diagnosed cases, access to the airway can be achieved at the time of cesarian section before clamping the umbilical cord (EXIT procedure), although emergent tracheostomy at the time of birth is rarely necessary.[45–47]

LMs involving the tongue pose a very difficult problem. As a general principle, direct surgical treatment of the tongue should be avoided if possible. Intermittent swelling of the tongue can be effectively controlled with systemic steroids. Capillary LMs involving the mucosal surface of the tongue (also known as simplex) can cause blistering, bleeding, and pain and are best handled with laser resurfacing techniques or bleomycin sclerotherapy.[77,85,86] Also, the use of laser technology for controlling airway obstruction from laryngeal or tracheal involvement has been highly successful in this group of patients. Persistent, symptomatic macroglossia involving the intrinsic muscles of the tongue may require reduction glossoplasty. LMs involving the floor of the mouth and tongue may also lead to bony malformations of the growing mandible, which may require subsequent surgical correction.[87]

Ultimately, the role of cosmesis in determining the extent of treatment is difficult to define. Severe LMs may be associated with significant social stigmatization, and this is of concern to patients and families alike.[88] However, because LM is a benign disease, gross total resection is not justified if it requires resection of vital structures. Thus, the treatment goal should be to restore function and adequate cosmesis while preserving important anatomic structures.[48]

LMs in the abdomen usually originate in the retroperitoneum or the intestinal mesentery. Choice of management depends on the type and extent of the lesion and can include surgical excision and/or sclerotherapy.[89] When surgical excision is chosen, either a laparotomy or a laparoscopic approach can be used. In either case, resection should be done using meticulous technique. Although a complete resection is sometimes possible, often some of the lesion must be left behind. Remaining cysts should be unroofed, since complications such as postoperative ascites are rarely seen. Primary intestinal lymphangiectasia presenting as a protein-losing enteropathy has been reported in case studies to be successfully treated with segmental resection of the most severely involved small bowel.[90] Occasionally, an LM will present with scrotal swelling and may be misdiagnosed and operated upon as a hydrocele. Once the diagnosis has become clear, these lesions should undergo complete resection if possible.

LMs of the extremities range from small, easily resected cysts to large, infiltrating lesions. The large malformations are often accompanied by poor lymphatic drainage, which predisposes the limb to edema, infection, and inhibition of function. Complete excision of these lesions may be impossible, and amputation may ultimately be necessary.

SURGICAL COMPLICATIONS

In the modern era, the mortality associated with surgical resection of an LM should approach zero. Early intervention before infectious complications or airway obstruction and strict adherence to the principles described here permit safe removal with little morbidity in the majority of cases. The complications of surgery include seroma, infection, and neurological sequelae such as Horner syndrome, facial nerve palsy, or spinal accessory nerve injury.

Recurrence can occur after surgical excision, especially if the first resection has been incomplete. These recurrences may represent fluid refilling cysts that had been decompressed, or may be due to filling of more distal cysts whose drainage has been interrupted by the surgical procedure. Ultrasound, CT, and MRI may all be useful for demonstrating these recurrent lesions. Options for management include further resection or injection sclerotherapy, depending on the anatomic location and the likelihood of injury to neurovascular structures.

CONCLUSION

LMs present as a clinically diverse spectrum of lesions arising at any anatomic location throughout the body. Lesions can be as simple as a single macrocyst of the neck or a

complex as a microcystic cervicofacial lesion with intracerebral and mediastinal extension. For complex lesions, there is no single treatment consensus, but a treatment algorithm must be established based upon the experience and strengths of a multidisciplinary managing team. Goals and limitations of treatment should be established via thorough discussions between the patient's family and all treatment providers.

Cervical teratomas

MICHAEL W. L. GAUDERER

INTRODUCTION

Cervical teratomas, although rare, are an important cause of neck masses in newborns and children. Because these lesions are often quite large, they can lead to precipitous airway obstruction necessitating prompt recognition and surgical intervention. Antenatal diagnosis and new techniques of multidisciplinary intrapartum management have contributed to an improved outlook for the survival of newborns at greatest risk of airway compromise.

PATHOLOGY

Teratomas are neoplastic lesions composed of tissues foreign to the anatomical site of origin, including all three germ layers. It is believed that most cervical teratomas arise from the embryonic thyroid anlage, although frequently, clear association with the gland cannot be demonstrated.[1–4] Roediger et al.[5] presented a comprehensive discussion of the histogenesis of this lesion in 1974. Although a wide variety of tissues from all three germinal layers have been found in cervical teratomas, there is a 68% incidence of neural tissue, which in many cases predominates in the solid portion of the tumor.[2–4,6] Thyroid tissue is present in 30% of specimens. The majority of cervical teratomas in the pediatric age group are benign (Figure 88.1a–c); however, malignancy with and without distant metastases has been reported.[3,7–9] Conversely, the incidence of malignancy in adults with cervical teratomas is reported to be as high as 70%.[10] Although cervical teratomas are generally located anteriorly to the major neck structures (Figure 88.2), significant distortions of normal anatomy are frequently encountered (Figure 88.3).[3,4,9,11,12] Teratomas are usually single lesions; however, they may occur in more than one site in the head and neck.[13] The presence of a teratoma arising in one fetus of a twin pregnancy has been described.[14] Associated anomalies are rare.[2–4]

INCIDENCE AND CLINICAL MANIFESTATIONS

In four large series of teratomas in infancy and childhood, the incidence of cervical location ranged from 2% to 9.3%.[15–20] Cervical teratomas are reported to occur in all races, and there is a slight female preponderance.[2–4] There is a high incidence of prematurity, polyhydramnios, and birth dystocia. Polyhydramnios is probably secondary to inability of the fetus to swallow amniotic fluid.[2] Stillbirth is usually associated with giant cervical lesions and due to a combination of compression of vital structures and congestive heart failure.[21] The most common clinical presentation, in addition to the mass, is respiratory difficulty.[1,4,12,22] Respiratory symptoms may vary from total apnea to mild dyspnea or coughing with feedings. The dyspnea may also be positional. Although airway compression may not be noted at birth, it may progress rapidly over several hours to a life-threatening obstruction. These cervical teratomas clearly represent a spectrum. Some children are referred beyond the neonatal period,[23] while in others, it only becomes manifest in adulthood.[3,10] A classification of cervical teratomas,[3] taking into consideration the age and clinical presentation (Table 88.1), clearly shows that almost half of the patients are newborns with respiratory distress (group II). Operative and nonoperative management was accompanied by a 43% mortality in this subgroup.[3] However, prenatal diagnosis, and more recently, the addition of intrapartum management, has markedly changed care and increased the survival rate, even for some of the highest-risk patients.[12,24–32]

DIAGNOSIS

Cervical teratomas can accurately be diagnosed antenatally[3,4,28] using ultrasonography,[28] which is the also the most useful immediate postnatal imaging study. Plain radiographs demonstrate calcification within the lesion in 16% of pediatric cases.[3,29] Tracheal deviation is common. Other imaging modalities such as radioisotope scans, computed axial tomography (Figure 88.3), and magnetic resonance

Figure 88.1 **(a)** One-day-old, full-term female newborn born with right cervical teratoma that extended into the oral floor, displacing the tongue to the left (arrow). The lesion was firm, partially cystic, and limited to the right anterior cervical triangle. She had mild respiratory distress, worsening when placed in the supine position. On the second day of life, the 6.5 × 5.5 × 4.5 cm mass was excised through a transverse cervical incision, combined with intraoral dissection. The thyroid gland was not involved. Analysis of the specimen revealed a benign cystic teratoma containing neuroglia, choroids plexus, smooth muscle, respiratory and squamous epithelium, and pancreas. Transient difficulty with oral feedings occurred in the immediate postoperative period. **(b)** Same child at 3 months of age. Notice the well-healed scar following the natural skin crease and the normal position of the tongue. **(c)** Same child at 6 years. The scar is no longer discernible. Tongue motion and dentition are normal.

Figure 88.2 Very large cervical teratoma in a premature child.

imaging (MRI) are helpful in more complex cases but should be used with great caution because sedation for longer exposure times may be needed. MRI can be helpful in planning the operation, as it demonstrates planes of dissection and position of vital structures that have been displaced by tumor growth.[7] It is also useful in the prenatal evaluation in preparation for operating on placental support.[30–32]

DIFFERENTIAL DIAGNOSIS

Differential diagnoses should include cystic hygroma, lymphangioma, branchial cleft abnormalities, congenital

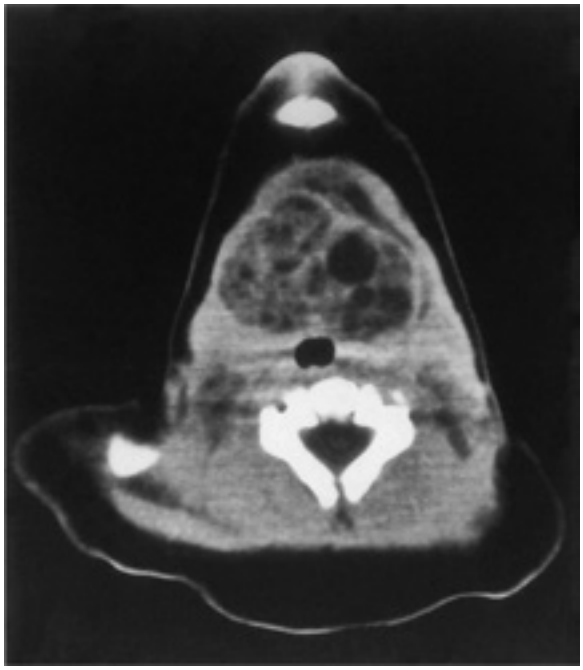

Figure 88.3 Computed tomography scan of the neck of a 5-month-old female patient. The lesion was initially thought to be a hemangiolymphangioma. Fortunately, this child had minimal or no airway compression, in spite of the location of the mass. The removed specimen was a benign teratoma containing neuroglia, choroid plexus, respiratory epithelium, pancreas, muscle, and cartilage.

Table 88.1 Classification of cervical teratomas by age and clinical presentation based on the review of 217 cases.[3]

Group	No. of cases	Total cases (%)	Malignant (%)	Mortality (%)
I Stillborn and moribund live newborn	27	12.4	2 (7.4)	100
II Newborn with respiratory distress	99	45.6	2 (2)	43.4[a]
III Newborn without respiratory distress	37	17.1	0	2.7
IV Children age 1 month to 18 years	31	14.3	0	3.2
V Adult	23	10.6	16 (69.6)	43.5[b]

[b] Incomplete follow up for six malignant cases.

goiter, thyroglossal duct cyst, dermoid cyst, neuroblastoma, and duplications.

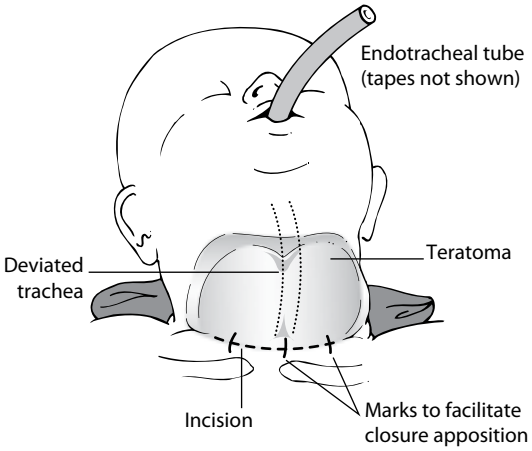
MANAGEMENT

The most difficult aspect of the management of orocervical teratomas is the establishment and maintenance of an adequate airway.[3,9,12,22] Orotracheal or nasotracheal intubation requires skill and patience in these infants due to tracheal deviation and/or compression. A useful adjunct is nasotracheal intubation with the aid of a flexible fiber-optic scope. The endotracheal tube is slipped over the scope, and the endoscope is then inserted. Once the tip of the flexible scope reaches the carina, the endotracheal tube is advanced and positioned. The distance between the carina and the end of the tube can then easily be determined by direct visualization. Tracheostomy, as an emergency procedure, has obvious limitations, although it may be necessary in extreme situations.[22,26] Whenever possible, a tracheostomy should be avoided because it increases operative as well as postoperative morbidity.[3] If the teratoma is composed of one or more large cysts, emergency aspiration may be employed to reduce tumor size and alleviate pressure on the airway.

An exciting advance in the management of fetuses with giant lesions and a high probability of upper-airway compromise at or immediately after birth is the development of the *ex utero* intrapartum treatment (EXIT).[12–32] This technique permits the establishment of a secure airway while the child is on placental support. The procedure requires a multidisciplinary approach of team members from the involved specialties: obstetrics, anesthesia, pediatric surgery, and neonatology.[24–27,30–32]

The incision for cervical and orocervical teratomas should be carefully planned to allow access not only to the neck but also to the upper mediastinum or oral cavity, if needed. As opposed to lymphangiomas, teratomas usually can be dissected without great difficulty (Figure 88.4a and b). The lesion is often attached to one of the lobes of the thyroid.

(a)



(b)

Figure 88.4 Operative approach to the case in Figure 88.3. The intubated child's neck is elevated over a roll **(a)**. Wide draping with adhesive plastic sheets allows for excellent exposure and helps prevent temperature loss. The incision is drawn with a marking pen on one of the skin creases, if possible **(b)**. To facilitate proper apposition of the redundant skin following resection, multiple small crosshatches are drawn with the pen. Following the skin incision, the marks are replaced by guy sutures, which are helpful for traction on the flaps, as well as the final approximation. It must be remembered during the dissection that the trachea may not be in the center. Other vital structures may also be markedly displaced.

When dissection reaches this level, every attempt should be made to preserve the thyroid and parathyroids. Dissection around the trachea and the esophagus must be carried out with great care to avoid injury to the recurrent laryngeal nerves (Figure 88.5). Tracheal as well as esophageal deviation should be constantly kept in mind. In the small neck of the newborn, deep dissection can lead to injury to the phrenic nerves. Once the tumor is removed, a soft, fine silicone rubber drain is placed and attached to a closed drainage system. The musculoaponeurotic layers are approximated with fine synthetic absorbable sutures, and the skin is closed with subcuticular stitches. Postoperatively, vocal cord and diaphragmatic function should be assessed and recorded. Calcium levels are measured in the immediate postoperative period, and thyroid function tests are obtained after a few weeks. Careful histological examination of the entire specimen is mandatory (Figure 88.6). If the alpha-fetoprotein levels were initially elevated, follow-up determinations should be sought.

Figure 88.5 Complete excision of a large cervical teratoma. Notice the smooth surface of the removed specimen and retraction of the redundant skin flaps by the guy sutures.

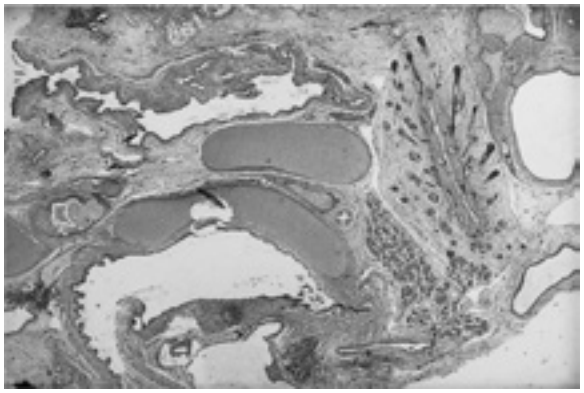


Figure 88.6 Histological section of a cervical teratoma demonstrating an array of various tissues.

CONCLUSION

The overall prognosis for cervical teratomas is good, particularly in the newborn with little or no respiratory distress (Table 88.1).[3,4,9,17,23] If the lesion is diagnosed *in utero*, appropriate preparations can be made to assure prompt establishment of a good airway immediately at or following birth. Carefully planned excision is then possible. This should increase the survival in the newborn with significant respiratory compromise.

Sacrococcygeal teratoma

KEVIN C. PRINGLE

INTRODUCTION

A sacrococcygeal teratoma (SCT) is a neoplasm arising from the caudal end of the spine, usually protruding from the inferior end of the infant's spinal column and displacing the anus forward. These tumors have a female-to-male ratio of at least 3:1.[1–9] The incidence is approximately 1 in 40,000 live births,[10,11] although a recent article from Finland[12] found a prevalence of 1:14,900 in a study that ascertained the prevalence in the total population, including terminations of pregnancies and stillbirths. There is general agreement that SCT is the result of continued multiplication of totipotent cells from Hensen's node that fail to apoptose at the end of embryonic life.[7,13,14] This concept has received support from the work of Busch et al.,[15] who have identified histochemical markers in SCTs supporting an origin from caudal embryonic stem cells. This provides convincing evidence against the theory that these tumors arise from migrating germ cells travelling from yolk sac to gonad. Economou et al.[16] recently reported a series of experiments in mice exploring the results of injecting pluripotent cells into early embryos. They found that expression of Oct4 and Nanog in the primitive streak/tail bud after the start of somitogenesis does not result in neoplasia. Most authorities reject the concept that these are suppressed twins or parasitic fetuses. In 1976, Pantoja and Rodriguez-Ibanez[17] reviewed the conflicting theories as to the origin of these tumors. Their findings still stand. Clearly, more studies are needed to determine the genetic influences that are associated with the formation of SCTs.

A familial distribution of SCT has occasionally been reported.[18–21] Interestingly, Sonnino et al.,[19] at least, didn't recognize the similarity of their family with the triad described by Currarino et al.[21] some 8 years earlier.

PATHOLOGY

Willis[14] defines the term *teratoma* as follows: "A teratoma is a true tumour or neoplasm composed of multiple tissues of kinds foreign to the part in which it arises." The SCT was second on Willis' list of sites where teratomata are found, but in almost all pediatric surgical series, the sacrococcygeal site is the most common site.[1–4,22] By definition, then, SCTs are composed of several types of tissue, usually derived from two or three germ layers. Robbins[23] defines a teratoma as "a tumour composed of cells representing more than one germ layer." In fact, however, in any tumor consisting of an epithelial component and a supporting stroma, at least two germ layers are represented. Most carcinomata, therefore, would meet Robbins's definition of a teratoma.

Within any one tumor, the cells can vary from totally benign (even forming well-formed teeth, hair, or other organs) to appearing frankly malignant (Figure 89.1). However, many SCTs contain malignant-looking cells (usually described as "immature"), but if they are completely excised, they do not recur. For this reason, the diagnosis of malignant SCT can only be made if there are distant metastases.[22]

The risk of malignancy depends on three factors: the site and the extent of the tumor and the age at diagnosis. Tumors diagnosed after 2 months of age have a high risk of being malignant. An exception to this statement is the relatively rare presacral "dermoid" tumors, which often present in adolescence or adult life with constipation or urinary obstruction but, if excised, completely appear to be totally benign. Altman et al.[22] classified SCTs into four groups when they reported the results of the American Academy of Pediatrics (AAP) Surgical Section survey (Figure 89.2). Type I tumors are almost exclusively exterior with a minimal pelvic component. They are rarely malignant (0% in the AAP survey). Type II tumors have a significant pelvic component. In the AAP survey, 6% of type II tumors were malignant. Type III tumors have an intrapelvic and intra-abdominal component greater than the external component. The intra-abdominal component can usually be palpated on abdominal examination. In the AAP survey, 20% of type III tumors were malignant. The type IV tumors are exclusively presacral; they had an 8% incidence of malignancy in the AAP survey.

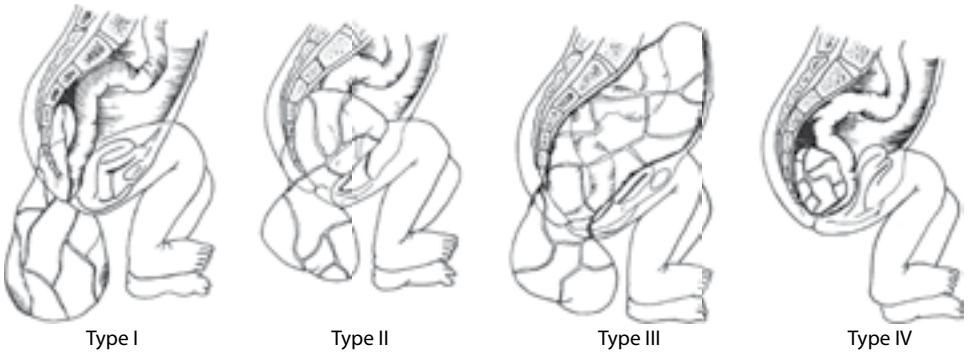

Figure 89.2 Sacrococcygeal tumors as classified by Altman et al. (From Altman RP et al., Sacrococcygeal teratoma: American Academy of Pediatrics Surgical Section Survey—1973, *J Pediatr Surg* 1974;9:389–98.)

PRESENTATION

Before routine antenatal ultrasound examinations became widely accepted, the most common presentation was as a large sacral mass that is immediately obvious at birth.[1–5,13,24,25] The malignant tumors tend to present as a swelling of the buttock at 5–6 months of age. However, with the advent of routine antenatal ultrasound, the most common presentation is now antenatal diagnosis by ultrasonography.[24–32] Series reporting the antenatal diagnosis of SCTs have revealed that many of those fetuses diagnosed as having an SCT are likely to die before delivery.[22,26,33–35] Most of the fetuses reported to have died following antenatal diagnosis had tumors with a mass as great as or greater than the rest of the fetus. It is, therefore, entirely possible that these fetuses die of heart failure as the fetal heart is unable to pump sufficient blood to nourish both the tumor and the rest of the fetus. Certainly, in most of the antenatal series reported, fetal hydrops (nonimmune hydrops) is very common and is associated with an increased risk of fetal demise.[24,27,29,31–36] In 1990, Ikeda et al.[31] reported characteristics of 20 cases of prenatally diagnosed SCTs. Six infants delivered at a gestational age of 25–32 weeks died perinatally; 14 cases delivered after 32 weeks' gestation survived. Other articles, including three from the group in Chapel Hill (all reporting the same nine antenatally diagnosed SCTs[37–39]) also report a high mortality rate if fetal hydrops is noted or if the diagnosis is made early in gestation.[31–36] Wilson et al., from the Children's Hospital of Philadelphia, have recently emphasized the rate of growth of the tumor and the estimated fetal cardiac output as important prognostic indicators, with a growth rate >150 mL/week and a combined cardiac output >650 mL kg^{-1} min^{-1} being associated with a worse prognosis.[40] Benachi et al.[41] and Coleman et al.[42] have similarly emphasized the prognostic importance of rapid fetal growth and high vascularity. More recent studies have emphasized the importance of the tumor-to-fetal weight ratio (TFR), with a TFR >0.12 before 24 weeks' gestation indicating a poor prognosis.[43,44] Fetal echocardiographic indicators of poor prognosis have also been described.[45]

Recent improvements in magnetic resonance imaging (MRI) technology have enabled this modality to be used in the fetus without the need for fetal sedation or paralysis.[46–48] More recently, Coleman's group[49] have used MRI to define the solid tumor volume, standardized to estimated fetal weight (solid tumor volume/estimated fetal weight), as another measure of prognosis. It is becoming easier to define the anatomy of the tumor much more accurately, and it is sometimes possible to accurately determine the blood supply to the tumor in utero.

The improved diagnosis and the high mortality rate associated with fetal hydrops have provided a considerable impetus for some groups to consider fetal surgery for selected cases of antenatally diagnosed SCTs. The groups

in San Francisco and at Children's Hospital of Philadelphia have had the greatest experience with this approach,[50–54] although other groups have also attempted fetal surgery[55] or percutaneous shunting or drainage to allow vaginal delivery[56,57] for these tumors. The results, so far, have been mixed.[50–57] A variety of other "minimally invasive" procedures, including radiofrequency ablation, laser ablation, and vascular embolization, have been attempted with relatively poor results in a poor-prognosis group of patients.[58,59] A detailed discussion of this aspect of the management of SCTs is beyond the scope of this chapter, but it would be fair to say that the role of fetal intervention for this tumor has still not been defined.

One further presentation (not often reported) is when the tumor becomes impacted during delivery. It either causes the death of the fetus by obstructing delivery or ruptures during delivery and the infant bleeds to death shortly after birth.[32,60–62]

CLINICAL FEATURES

Most cases presenting as neonates to pediatric surgeons will have a large skin-covered mass protruding from the coccygeal region, pushing the anus and vagina anteriorly (Figure 89.3). There may be large veins visible on the surface, and these usually drain into the surrounding structures. Large tumors may have ruptured (in which case they will bleed profusely) or may have an ulcerated area on the surface. Neonates with a tumor approaching the size of the rest of their body may be delivered prematurely and will often have some features of nonimmune hydrops.[25,27–33,35,36]

Infants presenting with malignant tumors usually present with a rapidly growing buttock mass.[63,64] In such cases, distant metastases are usually present at diagnosis. With the increasing use of antenatal ultrasound in many countries in recent times, this should become an extremely rare presentation. The management of these tumors is beyond the scope of this chapter. Recent advances in multimodal therapy of these tumors has resulted in survival rates as high as 80%.[65,66] Children and adolescents with a benign presacral tumor usually present with constipation or urinary retention.[18,20,22,67–69] A retrorectal mass is easily recognizable on rectal examination. Again, management of these tumors is beyond the scope of this chapter.

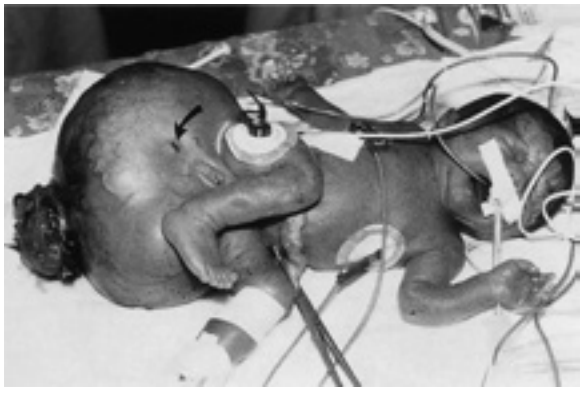

Figure 89.3 Premature infant with a large sacrococcygeal tumor that weighed almost as much as the rest of the infant. Note the displacement of the anus (arrow) and the vulva.

In all cases, the tumor is firmly attached to and may be said to arise from the anterior surface of the coccyx. It may displace the coccyx posteriorly, but almost without exception, the sacrum is normal. The author has seen one infant who was delivered at 30 weeks' gestation with a large SCT associated with agenesis of the coccyx and the last two sacral vertebrae.[29] Very rarely, however, the tumor can extend superiorly. In one reported case, the tumor extended within the spinal canal as high as T4,[70] and in another case, it resulted in permanent paraplegia.[71]

In most cases, the majority of the blood supply to the tumor is derived from the median sacral artery,[5,72] and during removal, once this vessel is controlled, blood loss is usually minimal. This is not always the case, and a preliminary abdominal procedure to control the median sacral artery in very large tumors, as suggested by some authors recently,[73–75] can occasionally yield very disappointing results, with only a very small vessel being identified.[76] In an occasional case, the feeding vessels have been embolized prior to attempting resection in a premature baby.[77] In addition, on two occasions in the current author's personal series, the bulk of the venous drainage from the tumor returned through the sacral hiatus and back to the azygous system via a large network of very friable epidural veins. This resulted in a frighteningly large loss of blood when the sacrum was divided. In both cases, the initial blood loss was controlled with pressure, and the middle sacral artery was rapidly controlled, allowing the definitive control of the bleeding from the divided sacral canal with Gelfoam on one occasion and bone wax on the other. With the improvement of the resolution of modern ultrasound machines and the introduction of color flow mapping using Doppler ultrasound, it should be possible to determine whether the venous return is via the sacral hiatus. The limited experience from the current author's center suggests that this is possible. However, it should be stated that in the patients in which preoperative color flow mapping has been used over the past 5 years, no sacral flow has been noted either on ultrasound or at operation. Clearly, more experience is needed. However, the simplicity of this examination with modern ultrasound machines makes this a useful addition to preoperative workup.

Some authors have advocated laparoscopic procedures to divide the middle sacral artery.[75] This may be technically difficult if there is a large intra-abdominal component of the tumor. Another recent paper[78] has emphasized the necessity of ensuring that the vessel to be controlled is, indeed, the median sacral artery.

POSTNATAL DIAGNOSIS

The major differential diagnosis that should be considered is an anterior meningocele. This can usually be ruled out

by physical examination, including rectal examination. In SCT, the rectal examination will invariably reveal a solid presacral component. If an anterior meningocele is present, this will be cystic, and an anterior sacral defect will often be palpable. Dillard et al.[4] point out the need to observe the anterior fontanel during the rectal examination. If an anterior meningocele is present, the diagnosis of Currrarino syndrome should be considered.[21,79] In anterior meningocele, pressure on the sacral mass will result in a bulging fontanel. The diagnosis can be confirmed by radiography of the lumbosacral region, which will show a characteristic defect in the sacrum in a patient with a meningomyelocele. An MRI examination will confirm the diagnosis.

Another recently described addition to the list of differential diagnoses is a sacrococcygeal chordoma.[80] Lemire et al.[81] have produced a list of 20 different lesions that can possibly enter into the differential diagnosis. Most of these are extremely rare but will usually be distinguishable from SCT on careful physical examination. An abdominal ultrasound is useful to determine the size and consistency of any pelvic or abdominal component. It may be necessary to pass a catheter into the bladder and fill the bladder with water to allow it to be used as a sonic window.

With the rapid improvements in MRI technology, it is now possible to utilize MRI in neonates with minimal sedation, although in many cases, a general anesthetic is still required for a detailed examination. Software packages allowing the use of MRI to delineate vascular anatomy are now available.[81–84] The use of gadolinium as a contrast medium has improved the delineation of the vascular anatomy. If oil is instilled into the rectum during the MRI examination while T_1-weighted images are gathered, then the oil can be used as a contrast medium during the scan,[85,86] although modern advances in MRI technology have now made this technique obsolete. MRI should clearly distinguish between SCT and anterior meningocele, and may be able to detect the occasional extension of the tumor through the sacral hiatus into the spinal canal.[70,71]

PREOPERATIVE MANAGEMENT

If the lesion is intact and the infant is stable, then there is no need for immediate resection. However, a case can be made for resecting these lesions within the first 24 hours after birth, since the gut is not usually colonized in the first 24 hours after birth. Early resection, therefore, will reduce the risk of infection if the field is contaminated by stool during the resection. Perioperative antibiotics are advisable. They should be given immediately before surgery commences and be continued for 24–48 hours postoperatively. If the infant has been fed, or is several days old, then a case can be made for a formal bowel preparation prior to the operation.

Blood should be cross-matched, and adequate intravenous access is vital. An arterial line may also be useful during the operation. It is worthwhile to obtain blood for alpha-fetoprotein (AFP) levels before surgery as a baseline, in order to confirm postoperatively that AFP levels continue to fall at a normal rate.[29,87–89] A recent paper from Italy[90] has advocated using an AFP >15,000 ng/mL as an indication for chemotherapy. In the author's opinion, this carries a significant risk of unnecessary chemotherapy. It should be noted that in very rare cases, the AFP level might not be elevated.[91]

If the tumor has ruptured, then a pressure bandage or transfixing sutures with felt pledgets,[92] may stem the blood loss for a brief time. However, there is some concern that this may "squeeze" immature cells into the venous drainage from the tumor. These cells will most likely lodge in the lungs. However, failure to slow the rate of blood loss in these infants may ensure that metastatic disease is not a problem for that infant. Obviously, emergency surgery is indicated in these circumstances.

In the past, there was often a reluctance to attempt the surgical removal of a tumor that might be as large as the rest of the baby. This is less common now, although there can be an understandable desire to let the baby grow before attempting the removal of the tumor, which will most likely be benign. This temptation should be resisted, however, as the risk of malignancy increases with age, suggesting that many of the tumors that were benign at birth become malignant after about 2 months.[3,5,7,8,13,18] If a surgeon in a peripheral hospital encounters one of these lesions, then transfer to a pediatric surgical unit is advisable, if this is possible.

OPERATION

The patient is anesthetized and intubated and a catheter placed in the bladder to measure urine output throughout the procedure, before being positioned prone with a roll under the hips. The roll is positioned so that the infant's weight is taken on the anterior superior iliac spines. It is vital that the abdomen be left hanging free to ensure that respiration is not inhibited by the baby's weight. For this reason, the baby's shoulders should be supported either by a smaller roll lying transversely across the apex of the chest at the level of the medial ends of the clavicles or by two rolls running parallel to the spine, each supporting the glenohumeral joints. The former option is illustrated in Figure 89.4. It is often useful to pack the rectum with Vaseline gauze to enable it to be readily recognized when the rectum is exposed later in the procedure. The packing also reduces the risk of stool contaminating the operative field. Many authorities state that the anus should be prepped out of the field.[13,93] This author finds that approach both inconvenient and impractical, as access to the anus is often required during the procedure. The cautery pad can usually be placed across the shoulders. A clear plastic drape may conserve body heat and assist in prevention of hypothermia. The addition of a perforated blanket through which is pumped warmed, filtered air also helps to maintain body temperature.

A chevron incision is made in the skin over the dorsum of the mass (Figure 89.5a,b), and it continues down to fascial layers. It is preferable not to dissect beyond the level of the deep fascia at this stage of the dissection. There are often several large veins in the subcutaneous tissue on either side of the midline; these should be cauterized, or if they are too

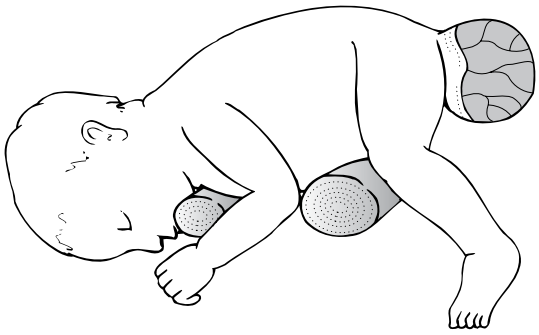

Figure 89.4 Infant with a sacrococcygeal teratoma positioned for surgical resection of the tumor. Note the large transverse roll under the pelvis and the smaller roll under the upper chest.

large for that, they may be divided between ties. The incision should be placed so as to preserve as much normal skin as possible. Excess skin can always be trimmed later if necessary. The apex of the chevron should be over the lower sacrum. In the midline, the dissection should continue directly down to the sacrococcygeal junction, or even down to the fourth or fifth sacral vertebra. The edges of the sacrum are defined, and a clamp is passed across the sacrum at the junction of the sacrum and coccyx, keeping the tips of the forceps against the ventral surface of the bone (or cartilage) to ensure that the forceps passes between the sacrum and the underlying median sacral vessels, which are usually substantial vessels, supplying the bulk of the blood supply to the tumor. Once this maneuver is complete, the sacrum (which is usually completely, or at least largely, cartilaginous) can be divided with a scalpel and the severed section of the spine displaced slightly inferiorly to expose the median sacral vessels (Figure 89.6a,b). As mentioned earlier, this can very rarely result in catastrophic blood loss from the epidural veins, if the bulk of the venous return is passing back to the baby via the sacral hiatus. It may be necessary to divide some of the attachments of the thinned-out remnants of the levators to the edges of the lower end of the sacrum and coccyx to enable the distal portion of the sacrum and coccyx to be displaced caudally. The median sacral vessels are then ligated in continuity and divided. This early division of the median sacral vessels is essentially the same as the procedure advocated by Smith et al.[72]

This maneuver opens a plane of dissection that is outside the tumor capsule but deep to the thinned-out remnants of the levators and gluteus maximus. The levators may be so thin as to be almost invisible (Figure 89.7), but they will contract on stimulation, with either a muscle stimulator or

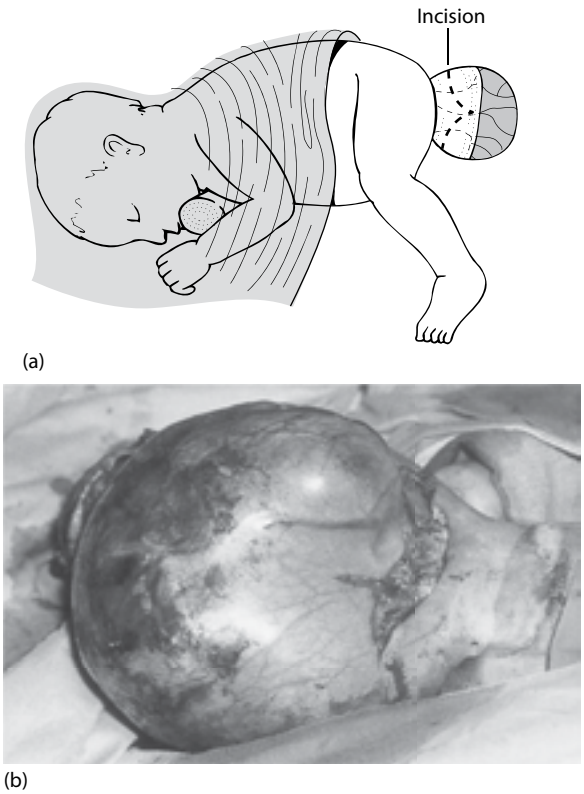

Figure 89.5 **(a)** Lateral view of the incision over the tumor. All normal skin that can possibly be preserved is retained, to be trimmed later if necessary. **(b)** Skin incision in the infant shown in Figure 89.3. Her head is to the right.

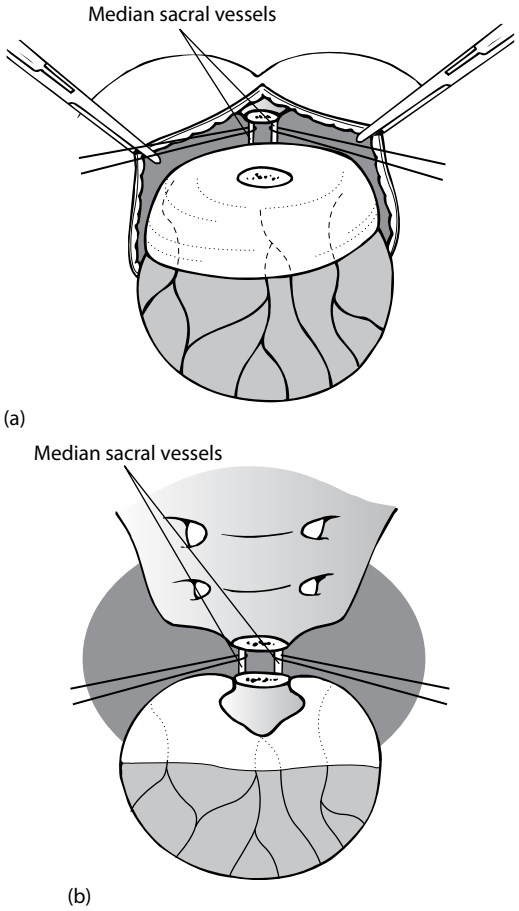

Figure 89.6 **(a)** Sacrum divided with the median sacral vessels slung on ties. **(b)** The divided fifth sacral vertebral body, showing the tumor arising from the ventral surface of the coccyx.

the electrocautery. The dissection should continue laterally in this plane either side of the midline until the muscles are lost in the fascia of the tumor. At this point, they can be divided along a line parallel to the skin incision. This will allow the tumor to be further displaced in a caudal direction.

Attention is then directed to the pelvic extension of the tumor. Using blunt dissection with peanut swabs in the plane anterior to the median sacral vessels, it is usually possible to displace the pelvic component of the tumor anteriorly until its upper extent is reached. This is normally an essentially avascular plane anterior to the sacrum, although some vessels feeding into the tumor from the internal iliac vessels may be encountered laterally. These can usually be controlled with cautery or ligated if necessary. In most cases, the tumor can be dissected out from the pelvis and rolled inferiorly over the patient's legs (Figure 89.8).

This maneuver exposes the upper end of the rectum, which can be identified by the Vaseline gauze pack placed immediately before the operation is commenced or by passing a finger or a Hegar dilator through the anus. The tumor can be dissected off the rectum with a combination of sharp and blunt dissection, and rolled inferiorly until the plane of dissection moves away from the rectum and the anal canal.

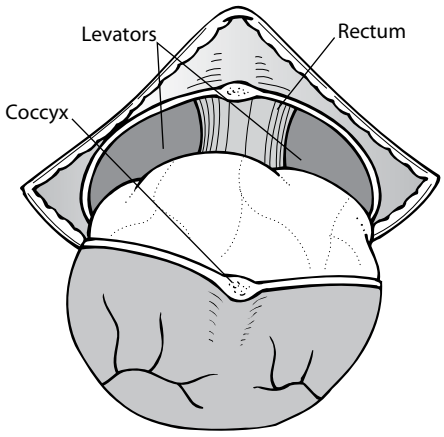

Figure 89.8 Completion of the pelvic dissection with the tumor rolled inferiorly, exposing the rectum.

At all times during this dissection, it is best to try to maintain the plane of dissection on the capsule of the tumor and to preserve all normal structures no matter how distorted and thinned-out they are. As the tumor is rolled inferiorly, it eventually becomes apparent that the plane of dissection has reached the subcutaneous tissue along the inferior surface of the tumor, posterior to the anus. Once the dissection has reached this point, the dissection can be terminated as long as the inferior skin flap that has been developed is of sufficient length to allow easy closure of the wound (Figure 89.9). The inferior skin flap can then be divided from the tumor and the tumor delivered from the field. A careful check of the tumor bed is carried out to ensure that meticulous hemostasis has been achieved. If the peritoneum has been opened during the pelvic dissection, then it is closed if possible.

Attention is then directed to reconstruction of the pelvic floor and closure of the wound. The remnants of the levator sling are identified, and the central portion is sutured to the perichondrium of the anterior surface of the sacrum using 5-0 Maxon (Cynamid Tyco Healthcare Group, Norwalk, Connecticut, USA) (a monofilament absorbable suture) (Figure 89.10a,b). This same suture is used for all subsequent muscle and fascial reconstruction. These initial fascial sutures, rather than the skin closure, should determine the siting of the anus. This aspect of the reconstruction, therefore, should be carried out with care to ensure both a functional and cosmetically pleasing result.

If a drain is to be placed, then it is placed at this stage, in the presacral space, led out through the gap in the levators, and tunneled out through the subcutaneous tissue of the buttock. A closed-suction drain is preferred. If there are remnants of the levators recognizable lateral to the midline, these are repaired with interrupted 5-0 Maxon sutures. The medial edges of the gluteus maximus are then closed in the midline over the sacrum and the lower part of the levator sling (Figure 89.11). The skin flaps are then trimmed to length. If possible, the subcutaneous tissues are closed with a running 5-0 Maxon suture, and the skin is closed

Figure 89.9 Completion of the pelvic dissection. The tumor has been dissected off the rectum (arrow), and the dissection has reached the stage where the division of the inferior skin flap can be contemplated. (Same patient as Figure 89.3; the head is to the right.)

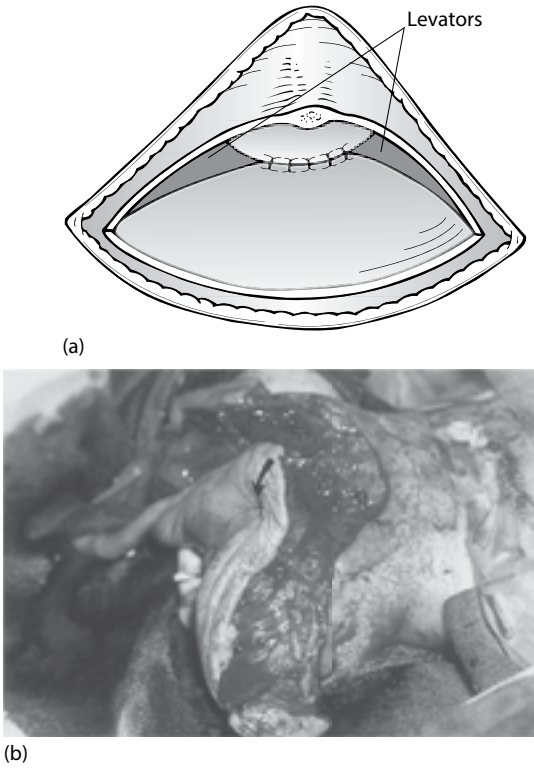

Figure 89.10 **(a)** Levators sutured to the perichondrium of the sacrum. These sutures set the anal position. **(b)** The levators have been sutured to the sacral perichondrium, resulting in the setting of the definitive anal position. (Arrow indicates the anus; same patient as in Figure 89.3; the head is to the right.)

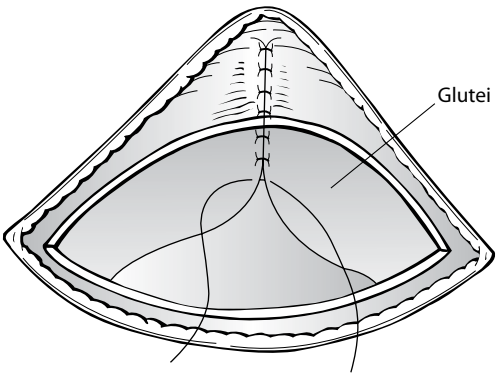

Figure 89.11 Closure of the glutei, posterior to the sacrum. This closure is continued inferior to the divided sacrum.

with a running 5-0 Maxon subcuticular suture. A Steri-Strip and collodion dressing is then applied. If it is not possible to close the subcutaneous tissue, then a subcuticular suture may not be adequate for skin closure. In this case, 5-0 nylon skin sutures are placed (Figure 89.12a,b). The rectum is repacked with Vaseline ribbon gauze at the completion of the procedure in an attempt to obliterate dead space. It is useful to attach a 2-0 silk suture to the end of this pack to aid its retrieval, should the pack become displaced higher up the rectum in the immediate postoperative period.

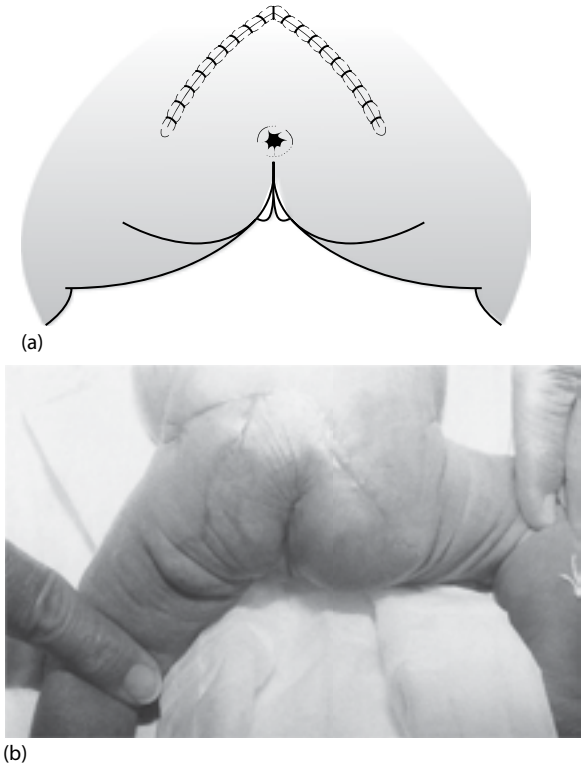

Figure 89.12 **(a)** Diagrammatic representation of the completed skin closure. **(b)** End result in the same patient illustrated in Figure 89.3.

Preliminary abdominal exploration is indicated in three circumstances:

1. If there is a large abdominal component[93,94]
2. If the tumor has been ruptured and is actively bleeding[76]
3. In the rare case when a premature baby is delivered in a hyperdynamic state and preliminary devascularization is needed to stabilize the patient before proceeding to definitive resection.[36]

In these cases, the abdomen is opened via a transverse infraumbilical incision placed just below the upper limit of any intra-abdominal mass or just below the umbilicus if there is no abdominal component. In either case, the aim is to find and ligate and then divide the median sacral vessels if at all possible. If this is not possible, then either an arterial occlusive sling[76] or a small vascular clamp is placed across the aorta below the origin of the inferior mesenteric artery. The abdomen is closed temporarily with a running 3-0 nylon mass closure and dressed with a clear plastic adhesive dressing. The patient is repositioned, and the tumor is then resected from behind as outlined previously. When the pelvic portion of the dissection is completed, the patient is repositioned in the supine position, and the clamp or aortic occlusive sling is removed before the abdomen is closed in layers with 4-0 Maxon sutures to the fascia and 5-0 Maxon subcuticular sutures to the skin. As noted previously, this procedure has been performed laparoscopically.[75,78]

Some authors[74] have advocated an abdominoperineal approach in all cases with routine devascularization of the tumor through an abdominal approach, followed by resection of the tumor (under the same aesthetic) with the patient in the supine position. Others have recently described a posterior midline approach, with the patient prone.[95] Some surgeons in Melbourne (B. Bowkett, personal communication) also advocate resection of the tumor in the supine position, with the initial incision being in the midline, extending from the sacrum down to the tumor. These authors cite the ability to devascularize the tumor from the abdominal approach and the ease with which external cardiac massage can be applied as the main advantages of this approach. The current author retains significant reservations about this approach. There is a need to control the blood supply to the tumor from above in a minority of cases, and it is felt that if there is a significant venous drainage through the epidural veins, then blood loss from this source would be extremely difficult to control with the patient in the supine position.

POSTOPERATIVE MANAGEMENT

The infant is nursed in a prone position for several days postoperatively. The urinary catheter can be removed as soon as the baby's condition is stable, and the infant can be extubated as soon as his/her respiratory condition allows. The infant can usually be fed as soon as he/she is extubated. The Vaseline pack is usually removed on the first postoperative day by pulling on the 2-0 silk suture left attached to the distal end. Any drain can usually be removed within the first few days of the procedure. A recent paper reported an unusual rare complication of a postoperative epidural hematoma that resulted in a cauda equina syndrome.[96] The patient presented 17 days after a late (11 months of age) resection of an SCT with a distended bladder, loss of rectal tone, and significant weakness of the lower limbs. After emergency surgery, the patient eventually made a full recovery.

AFP levels should be determined immediately postoperatively and on discharge. In spite of the fact that AFP is stated to have a half-life of only 3 days, the levels usually take several months to return to normal. The infant should then be followed at monthly intervals for 3 months and then at 3-month intervals for 1 year. At each visit, a rectal examination will detect any local recurrence, and an AFP level will detect any distant spread. The AFP level is often very high (of the order of 100,000 IU or more[29,87]), and even in normal babies, it may be over 100,000 IU.[87–89] These high levels usually take over a year to fall to normal adult levels. As long as the AFP level continues to fall steadily, recurrence is thought to be unlikely. However, it is important to not rely solely on the AFP levels, as in one patient in the current author's series, a very large pelvic recurrence (sufficiently large to produce urinary obstruction) occurred in the presence of a continuously falling AFP level. None of the other patients who developed recurrent tumors (including the patient who developed metastases in the inguinal lymph nodes) showed a rise in the AFP levels.

Follow-up should continue for at least 5 years, and preferably through puberty, if at all possible. It is important to obtain renal ultrasounds on an annual basis for the first few years and vital to obtain one on an urgent basis if there are any new urinary symptoms. One patient in the current author's series had a normal renal ultrasound close to her second birthday in April. In September of that year, she presented for routine follow-up with a history of having had three urinary tract infections in the last 2 months. A renal ultrasound obtained shortly after that visit revealed severe hydronephrosis bilaterally, and her serum creatinine level was significantly elevated, having been normal only a few months before. Urodynamic studies revealed that she had a hostile, high-pressure neurogenic bladder. The hydronephrosis resolved considerably with the introduction of clean intermittent catheterization, although this has placed a considerable strain on the family.

PROGNOSIS

In the absence of distant metastases at presentation, and if the excision is complete, then the life expectancy should be normal, although the appearance of the buttocks usually leaves something to be desired (Figure 89.12b).

There has been a flurry of recent papers in the literature that focus on long-term outcome. One paper[65] reported the results in a series of 23 patients followed for up to 22 years. Four patients with malignant tumors had recurrence-free intervals ranging from 9 to 14 years. They had two patients with nocturnal enuresis, one of which had perineal anesthesia. They had one child with a patulous anus and one patient with a neurogenic bladder. They emphasized the need for long-term follow-up and the need to be alert for the late appearance of urinary or fecal incontinence.

Another paper, from Liverpool, reports the results in 33 patients over 25 years treated in a single center.[97] Surprisingly, only one patient was described as having an immature teratoma, and six patients were described as having malignant tumors, two of whom died of metastatic disease. Some of the other patients in this report appear to have been diagnosed as having malignant tumors on the basis of histology and were then treated with chemotherapy on the basis of that diagnosis. In the author's series, there have been local recurrences treated only by repeat resection, without any adjuvant therapy. The only patient treated with chemotherapy was the patient who presented 2 months after resection with evidence of spread to the inguinal lymph nodes. She is a long-term survivor 18 years after a course of intensive chemotherapy.

Several other recent papers stress the need for close follow-up to detect the relatively high incidence of abnormalities of the genitourinary tract[98] and late-presenting urinary complications.[99–102]

Other papers[97,103–108] have focused on the longer-term outcomes. Overall, the quality of life in long-term survivors seems to be very good,[103,104] although some papers highlight

constipation or wetting occurring with urinary and/or fecal incontinence in up to 30% of patients.[97,105,106] Another paper reports a series of 13 women who successfully delivered a baby after having an SCT excised in infancy.[107] Interestingly, the vast majority successfully delivered vaginally. One interesting case report detailed a woman who had had an SCT excised in infancy and suffered a genital prolapse in her twenties.[108]

There are mixed reports on the risk of recurrence and the incidence of malignancy. Some papers appear to rely on the histological appearance or the AFP level to diagnose malignancy.[90,109,110] The author reiterates that both recurrence and malignancy can appear in the face of a falling AFP. A paper from Japan,[110] however, does point out that malignant yolk sac tumor can appear up to 30 months after total resection in infancy, apparently arising from tumors that were entirely benign at the initial resection. Another paper[111] suggests adding CA 125 to the battery of surveillance tests. In their series of 32 patients, the CA 125 was elevated in in one-third of mature and one-third of immature recurrences.

The prognosis for patients presenting with a malignant SCT must still be guarded. Modern chemotherapy has produced a considerable improvement in survival.[62,112] The chemotherapy regimens are relatively toxic, and these patients require close monitoring during their treatment. Survival rates as high as 80% have been recorded.[62] De Corti's group[90] has recently reported survival rates of 89%. However, it appears that some of their neonatal patients were treated with chemotherapy on the basis of an AFP >15,000 ng/mL and/or histology indicating germ cell or yolk sac tumors. This may explain some of this improved result. Interestingly, although presacral tumors tend to present with malignant transformation, those found in patients with Currrarino syndrome tend to have a much better prognosis.[113]

Nasal tumors

UDO ROLLE

INTRODUCTION

Congenital masses of the nasal midline are very rare, occurring in 1 in every 20,000–40,000 newborns. Although benign, these masses may cause large facial deformities such as hypertelorism, cerebrospinal fluid (CSF) fistulas, cerebral herniation, visual alterations, meningitis, and cerebral abscess.[1,2]

There are various types of congenital nasal tumors. They may be classified in accordance with their embryonic origin; the most common are nasal dermal sinus, nasal glioma, and anterior encephalocele (Table 90.1).[1–5]

EMBRYOLOGY

At an early stage of development during the third and fourth weeks, there is a protrusion of the forebrain and dura through the foramen cecum into the prenasal space, which is limited by frontal and nasal bones on the anterior aspect and posteriorly by a cartilaginous capsule. During further development, the dural process is sealed, and the foramen gets obliterated. Any failure of this obliterating procedure leaves a canal, a pathway favoring the extension of the glial tissue, hence the development of encephaloceles and gliomas.[6]

An *encephalocele* is a herniation of brain tissue into the prenasal space; a *glioma* is derived from an encephalocele sequestered from the brain; for some authors, gliomas are hidden encephaloceles or sequestered encephaloceles.[7]

The frontal and nasal bones are formed by intramembranous ossification. At this stage of development, there is a gap between these bones, the fonticulus nasofrontalis, filled by a membrane; the dura and the skin are in contact without interposition of bony tissue. Part of the ectoderm may fail to separate from the dura and so remain in the depth of the nasal space. This displaced ectopic ectodermal tissue is the origin of a *dermoid cyst*. If a connection does exist with the skin, a *dermoid sinus* will result.

All these tumors or heterotopias are located in the midline (nasofrontal) or asymmetric unilateral (nasoethmoidal) position. They are present at birth. They often produce hypertelorism, telecanthus, and nasal deformity.

CONGENITAL TUMORS OF NEUROGENIC ORIGIN

Nasal glioma

Gliomas of the nose are rare, always benign heterotopias; they should not to be considered as tumors. Approximately 250 cases of nasal glioma have been described in the literature.[8] Their incidence is 1 in 250,000 births, with a male-to-female ratio of 3:1.[9,10] Nasal gliomas account for approximately 20% of all congenital nasal masses[11]; 60% of the tumors are extranasal, while 30% are intranasal and 10% both.[1,12,13] Although most gliomas are located around the midline region of the nose, there are reports with gliomas located in the scalp, cheek, soft palate, tonsils, tongue, leptomeninges, middle ear, orbit, and limbal dermoids.

A nasal glioma is a firm, gray-pink to purple, rounded or dome-shaped polypoid, noncompressible, and nonpulsatile mass of glial tissue of congenital origin that may appear in an extranasal or intranasal location at or near the root of the nose (Figure 90.1). It shows no impulse when the patient cries. The covering skin may look like a hemangioma. Gliomas are unilateral or in the midline, but are usually located at the side of the nasal bridge. The root of the nose is often enlarged; there may be an orbital hypertelorism. The diameter of the tumor varies from 1 to 3 cm. Their growth rate is usually the same as that of the surrounding tissue according to the infant's growth.

The intranasal type is located high in the nasal fossa. The septum may be displaced, and the nasal passage may be obstructed. Increased lacrimation may result from compression of the lacrimal duct. These tumors may present as early neonatal respiratory distress.[14]

• Hemangioma
• Vascular malformation
Mixed origin
• Teratoma

In intra–extranasal gliomas, there is a communication between the two components of the mass, usually through a defect in the nasal bone or at the lateral margin of the nasal bone.

HISTOLOGY

A glioma consists of glial and fibrous tissue with an overlying flattened epidermis.[12] The specimens consist of fibrillary astrocytes and fibrous connective tissue. True neurons are seen rarely.[15] It does not contain CSF-filled space communicating with the ventricular system of the brain or the subarachnoid space. In two heterotopias, cellularity in places approached that of low-grade neoplastic glioma.[16]

Figure 90.1 Nasal glioma in a newborn.

DIAGNOSIS—IMAGING

Preoperative imaging is essential for an appropriate surgical approach by delineating the exact site and extension of the tumor.[12,17] It is important to distinguish nasal tumors or masses from basofrontal encephaloceles to avoid inadvertent exposure of the brain during the surgical removal of mass lesions.

Computed tomography (CT) scanning is useful to visualize bony defects but is not reliable for soft-tissue contrast. Magnetic resonance imaging (MRI) is superior for imaging brain tissue; it should therefore be used preferentially for definition of the tumor mass and to disclose intracranial extension.[5,17]

TREATMENT

Though benign and relatively slow growing, these heterotopias can cause disturbances of growth and subsequent deformity by encroachment upon the bony frameworks of the nose. Furthermore, they are unsightly, and some of them, located at the root of the nose such as encephaloceles and gliomas, may interfere with vision. Hence, early surgical excision is advisable.

Complete surgical excision of nasal gliomas—with repair of any hypertelorism—is the treatment of choice. The most conservative cosmetic surgical technique should be chosen after intracranial connection has been ruled out.

TECHNIQUE

An elliptical incision is made around the base of he tumor, and the mass is removed in toto. In order to avoid recurrences, it is important to excise or coagulate the small deep stalk, which may pass upward for a short distance under the nasal bone. This tract is exposed by splaying open the nasal bones through a midline nasal incision. In the case of a high-situated intranasal glioma, an extracranial extranasal approach may be necessary to provide wide access to the nasal cavity. A lateral rhinotomy is most often used. Burckhardt and Tobon[18] described an endoscopic approach in the case of an intranasal glioma. In cases with intracranial lesion, craniotomy is mandatory.

COMPLICATIONS

Incomplete excision

Recurrences due to incomplete excision are rare (11%). In 13% of the cases, there is a connection with the intracranial nervous system by a pedicle of fibrous tissue, passing through the cribriform plate. Nasal gliomas with a cystic component seem to have a greater tendency for recurrence; the reason for this remains unclear[19] Levine et al. reported a case in which a nasal glioma masqueraded as a capillary hemangioma with subsequent inadequate treatment, which indicates the eventual need for a preoperative histologic examination in some cases.[15]

A recurrence can be avoided by a detailed evaluation of the preoperative imaging and a meticulous dissection in

order to expose a stalk or a possible intracranial connection. Only a complete excision prevents recurrence.[19–21]

Dural defect

As normally there is no permeable communication with the subdural space, an accidental dural defect is theoretical. Should it occur, it must be promptly closed to prevent a CSF fistula. If such a defect is large, an epicranium graft may be needed for a safe and tight closure.

Hematoma

This can be avoided by careful hemostasis with bipolar coagulation.

Skin defect

In some cases, the skin defect is closed directly. Large defects can be covered by free-skin grafting, by glabellar skin flaps, or by tissue expansion (Figures 90.2 through 90.4).

Meningocele and encephalocele

The encephalocele is a protrusion of the brain inside a dural sac through a skull defect. The tumor contains an ependyma-lined space filled with the CSF; it communicates with the ventricular system. Encephaloceles are located at the root of the nose, midline (nasofrontal) or asymmetric lateral (nasoethmoidal); they are most frequently intranasal.[1,22] The bridge of the nose is broadened, and often hypertelorism, and nasal deformity are produced. Depending on the contents, meningoceles and encephaloceles are taut of soft, compressible, and pulsatile tumors, enlarging when the patient cries (Fürstenberg sign).

Evaluation should include a complete rhinologic and neurologic examination.[23] The dominant clinical sign of encephaloceles is an intermittent rhinoliquorrhea that can be distinguished from normal nasal secretion by the typically high glucose concentration in the liquor. The defect at the base of the skull is demonstrated by radiological examination; an intracranial lesion is best disclosed with MRI and/or CT scanning.[24] 3-D CT provides additional useful information in cases with significant bony abnormalities at little additional cost or time.[25]

TREATMENT

The treatment of choice is excision of the tumor with the herniated brain and closure of the dural defect. Usually, there are no problems for closure of the wound, the covering skin being normal. According to Macfarlane et al., primary and secondary hypertelorism regressed in most instances where patients were treated before the age of 2 years.[26] In their series of 114 patients treated in a 15-year period, in 59% of the children, the developmental outcome was normal, 18% have mild mental or physical disability, and in 23%, severe impairment occurred.

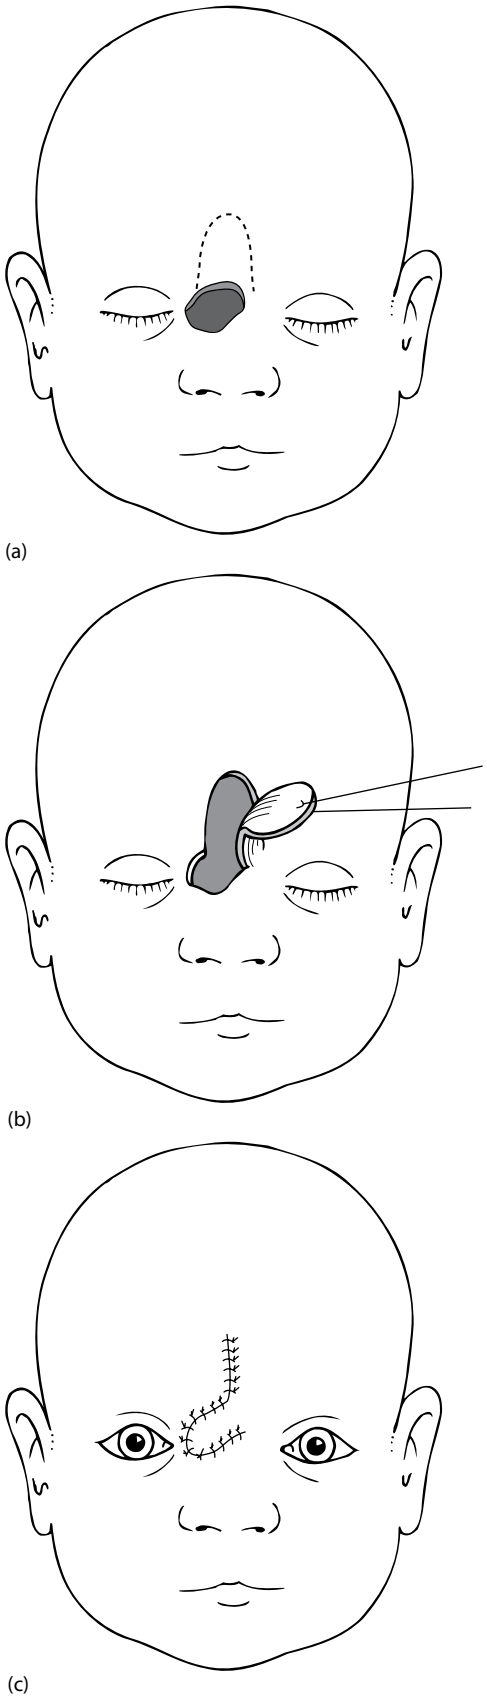

Figure 90.3 Finger flap—midline transposition flap. **(a)** Incision, **(b)** mobilization, and **(c)** result.

The main postoperative complication is leakage of CSF because of a large dural defect.[23,26] In the series of Macfarlane et al.,[26] it occurred in 1 patient out of 114. The dural defect must be closed tightly to prevent such a fistula. If the defect is too large for direct closure, an epicranial or a fascia lata graft may be a valid alternative.

CONGENITAL DERMOID CYSTS AND DERMOID SINUS

Congenital dermoid cysts are the most frequently found congenital nasal tumors. During early embryonic development, a portion of the dura begins to grow in close association with nasal skin. Eighty-four percent are found in the head and neck, 37% of these are located in the orbit and periorbit, and 10% are found in the midline of the nasofrontal region. External dermoid cysts present clinically as a firm, nonfluctuating, and nonpulsatile mass. The Fürstenberg sign is negative.[1] The dermoid sinus appears externally sometimes as a dimple with protruding hair; in these cases, only a thorough examination will bring up the diagnosis. The dimple usually leads to a sinus tract, which extents along the nasal septum, underneath the nasal bones, toward the base of the anterior cranial fossa; it may enter the skull (dumbbell cyst).[5] Imaging comprises CT and MRI.[27]

Nasal dermoids can be classified into superficial, intraosseous, intracranial extradural, and intracranial intradural. This classification allows precise surgical planning.[28]

Dermoid cysts and sinuses are both lined by squamous epithelium with various dermal appendages such as glands and hair follicles.

Repeated infections may form multiple sinus tracts, making complete excision difficult. Sometimes the mass of the cyst may erode nasal bones and associated sinuses. Although rare, liquorrhea may occur.

Treatment

The treatment of choice is operative removal, preferably before potentially chronic infections occur.

Technique

A midline nasal incision and excision of the mass is the best technique. The tract passing into the nasal septum must be exposed after opening the nasal bones. All epithelial elements must be removed. The stalk is carefully dissected cephalad; if it enters the skull, a craniotomy is mandatory in order to remove the intracranial part of the lesion.[29]

NASAL TERATOMA

Teratomas are rare in children. They arise from one or a combination of the three embryonic layers and could be classified as either mature, immature, or malignant. Head

and neck teratomas account for only 0.47%–6% of all teratomas; nasal teratomas are much rarer.[30]

Most nasal teratomas will be visible immediately after birth.

Diagnosis will be completed by imaging (CT, MRI).

Treatment

Complete surgical excision is the required treatment. In cases with nasopharyngeal teratomas obstructing the airway, an ex utero intrapartum (EXIT) procedure will be required (Figure 90.5).

Neuroblastoma

ANDREW M. DAVIDOFF

INTRODUCTION

Cancer in the newborn is relatively rare, comprising only about 2.5% of all childhood malignancies[1]; the majority of tumors in the newborn are benign lesions. Overall, neuroblastoma is the fourth most common cancer of childhood, accounting for about 8% of all malignancies diagnosed in children younger than 15 years of age. Neonatal neuroblastoma, defined as neuroblastoma diagnosed prenatally or within 30 days after birth, accounts for approximately 5% of all cases of neuroblastoma.[2] However, neuroblastoma is second only to teratoma as the most commonly diagnosed tumor in the neonate and is, overall, the most common malignancy in the newborn, accounting for 30% of all cancers diagnosed in this age group. With the increasing use of perinatal imaging, the incidence of neonatal neuroblastoma is very likely to increase.

Neuroblastoma is a heterogeneous disease; tumors can spontaneously regress or mature without treatment, or display a very aggressive, malignant phenotype. Although the specific reasons for these differences in biologic behavior have yet to be completely elucidated, certain clinical and biologic factors have been identified that predict, to a significant degree, the tumor phenotype. Among these, patient age at diagnosis is one of the most powerful, with age less than ~1½ years conferring a favorable prognosis.[3] It follows, then, that neuroblastoma diagnosed in the newborn period is associated with a very favorable outcome. Overall, the 5-year survival for children with neuroblastoma is 79%,[4] while neonates have a 5-year survival of 85%–90%.[5,6] The challenge in managing these patients is to maintain the excellent survival rate while minimizing the toxicity of therapy.

ETIOLOGY

Neuroblastoma is an embryonal tumor that arises from neural crest cells. During normal development, neural crest cells migrate from the developing neural tube to form the sympathetic nervous system. Thus, neuroblastoma can originate anywhere along this path of migration in the neck, chest, abdomen or pelvis, including the adrenal medulla, paraspinal sympathetic ganglia, and sympathetic paraganglia, such as the organ of Zuckerkandl. Although the precise etiology of neuroblastoma is currently unknown, as with all cancer, genetic (both inherited and somatic), epigenetic, and environmental factors appear to contribute.

Inherited genetic factors

Neuroblastoma generally occurs sporadically, but familial neuroblastoma does occur in about 2% of the cases. Interestingly, however, substantial biologic and clinical heterogeneity is often observed within familial cases. The germline mutation associated with hereditary neuroblastoma has been identified—activating mutations in the tyrosine kinase domain of the anaplastic lymphoma kinase (*ALK*) oncogene on the short arm of chromosome 2 (2p23).[7] These mutations can also be somatically acquired, although the prevalence of ALK activation in sporadic neuroblastoma remains to be determined.

Somatic genetic factors

Although there is no single genetic abnormality or initiating event common to all neuroblastomas, a number of different genetic alterations have been identified that provide powerful prognostic information and play crucial roles in risk assessment and treatment planning.

DNA Content. Normal human cells contain two copies of each of 23 chromosomes; thus, a normal diploid cell has 46 chromosomes. The majority (55%) of primary neuroblastomas are triploid or *near-triploid/hyperdiploid* and contain between 58 and 80 chromosomes; the remainder (45%) are either *near-diploid* (35–57 chromosomes) or *near-tetraploid* (81–103 chromosomes).[8] The *DNA index* of a tumor is the ratio of the number of chromosomes present to a diploid number of chromosomes (i.e., 46). Therefore, diploid cells have a DNA index of 1.0, whereas near-triploid cells have a DNA index ranging from 1.26 to 1.76. Importantly, patients

with near-triploid tumors typically have favorable clinical and biologic prognostic factors and excellent survival rates, as compared with those patients who have near-diploid or near-tetraploid tumors. This association is most important for infants with advanced disease[9]; the prognostic significance of tumor ploidy appears to be lost in patients older than 2 years of age.

Amplification of MYCN. Early studies of neuroblastoma cell lines showed the frequent presence of extrachromosomal double-minute chromatin bodies (DMs) and chromosomally integrated homogeneously staining regions (HSRs) characteristic of gene amplification.[10] Since that time, it has been shown that the amplified region was derived from the distal short arm of chromosome 2 (2p24) and contained the *MYCN* proto-oncogene.

Overall, approximately 25% of primary neuroblastomas have *MYCN* amplification, being present in 40% with advanced disease but only 5%–10% with low-stage disease.[11] The copy number, which can range from 5- to 500-fold amplification, is usually consistent among primary and metastatic sites and at different times during tumor evolution and treatment. This finding suggests that *MYCN* amplification is an early event in the pathogenesis of neuroblastoma. Amplification of *MYCN* is associated with advanced stages of disease, rapid tumor progression, and poor outcome; therefore, it is a powerful prognostic indicator of biologically aggressive tumor behavior.[11,12]

Chromosomal Changes. Approximately 20–35% of primary neuroblastomas exhibit 1p deletion, as determined by fluorescence in situ hybridization (FISH), with the smallest common region of loss located within region 1p36.[13] About 70% of advanced-stage neuroblastomas have 1p deletions. Molecular studies have shown that there is a strong correlation between 1p deletion and *MYCN* amplification and other high-risk features such as age older than 1 year and advanced-stage disease.[13] One study has demonstrated that 1p deletions are independently associated with a worse outcome in patients with neuroblastoma.[14] Deletion of the long arm of chromosome 11 (11q) also appears to be common in neuroblastoma, being present in about 40% of cases. Unbalanced deletion of 11q (loss with either retention or gain of 11p material) is inversely related to *MYCN* amplification[14,15] yet is strongly associated with other high-risk features. Other studies have shown that gain of genetic material on the long arm of chromosome 17 (17q) is perhaps the most common genetic abnormality in neuroblastomas, occurring in approximately 75% of primary tumors.[16] It is unclear at this time how extra copies of 17q contribute to the malignant phenotype of neuroblastoma and which genes on 17q are the critical ones. Nevertheless, gain of chromosome 17q is strongly associated with other known prognostic factors, but it may also be a powerful predictor of adverse outcome.[17]

Epigenetic factors

Epigenetic alterations are defined as those heritable changes in gene expression that do not result from direct changes in DNA sequence. Mechanisms of epigenetic regulation most commonly include DNA methylation, modification of histones, and alterations in microRNA (miRNA, a class of noncoding RNAs) expression. Each of these is likely involved in neuroblastoma pathogenesis.[18] For example, promoter methylation resulting in silencing of caspase 8, a protein involved in apoptosis, likely contributes to the pathogenesis of *MYCN*-amplified neuroblastoma.[19] Also, analyses of miRNA expression has demonstrated that many miRNAs are dysregulated in neuroblastoma,[20] where they frequently lose their function as gene silencers/tumor suppressors.

Environmental factors

In addition to genetic factors, environmental factors may have a direct impact on cell phenotype and fate by causing DNA damage that permanently alters the host genome, although few environmental factors have been convincingly linked to the development of neuroblastoma. Several case–control studies have examined the relationship between maternal and paternal occupation and exposure, and the risk of neuroblastoma in offspring.[21] Several other studies have also suggested a relationship between the use of certain medications just prior to and during pregnancy and neuroblastoma, specifically hormone use and fertility drugs, and phenylhydantoin for seizure disorders.[22] Similarly, the results for smoking, alcohol, illicit drug use, and the use of hair dye in some studies are suggestive but not conclusive.[23]

EVALUATION

Presentation

When symptomatic, children with neuroblastoma usually present with signs and symptoms that reflect the primary site and extent of disease. An abdominal mass may be detected on physical examination when the primary is adrenal or retroperitoneal. Respiratory distress may be a reflection of a thoracic tumor. Altered defecation or urination may be caused by mechanical compression by a pelvic tumor, or by spinal cord compression by a paraspinal tumor. A tumor in the neck or upper thorax can produce Horner syndrome (ptosis, miosis, and anhydrosis), enophthalmos, and heterochromia of the iris. More general signs and symptoms that reflect excessive catecholamine or vasoactive intestinal polypeptide secretion include failure to gain weight, hypertension, and diarrhea.

However, newborns with localized disease, especially those whose lesion was detected on routine perinatal imaging, are almost always asymptomatic. Paravertebral tumors presenting with spinal cord compression (a clinical emergency requiring immediate evaluation) with flaccid leg paralysis and bladder and bowel dysfunction were reported in one series in less than 20% of patients with neonatal neuroblastoma.[24] Although very uncommon, neonatal patients can also present with paraneoplastic syndromes such as opsoclonus–myoclonus–ataxia felt possibly to be secondary

to a cross-reactivity of antineuroblastoma antibodies and Purkinje cells in the cerebellum. Two-thirds of these cases occur in infants with mediastinal primary tumors.[25] Although the oncologic outcome for these patients is generally very favorable, neurologic sequelae may persist.

Approximately 35% of infants with neuroblastoma will have metastatic disease at presentation, although greater than two-thirds of these will have a "special" stage of metastatic disease, which, by definition, is a localized primary tumor in patients younger than 1 year, with dissemination limited to skin, liver, or bone marrow (<10% of nucleated cells). These patients may present with "blueberry muffin" cutaneous lesions, respiratory distress secondary to massive hepatomegaly, or anemia secondary to bone marrow disease (see section "Special Considerations in Infants: Stage 4S neuroblastoma").

Laboratory findings

Lactate Dehydrogenase. Despite its lack of specificity, serum lactate dehydrogenase (LDH) can have great prognostic significance. High serum levels of LDH reflect high proliferative activity or large tumor burden, and an LDH level higher than 1500 IU/L appears to be associated with a poor prognosis.[26] Thus, LDH can be used to monitor disease activity or the response to therapy.

Ferritin. High levels of serum ferritin (>150 ng/mL) may also reflect a large tumor burden or rapid tumor progression. Elevated serum ferritin is often seen in advanced-stage neuroblastomas and indicates a poor prognosis[27]; levels often return to normal during clinical remission.

Urinary Catecholamines. Measurement of homovanillic acid (HVA) and/or vanillylmandelic acid (VMA) in the urine is a critical component of the preoperative assessment. Together with a positive bone marrow, elevated levels can be used to make the diagnosis of neuroblastoma and, if elevated at diagnosis, can be used as a marker of disease status (e.g., progression or recurrence).

Diagnostic imaging

Standard Radiographs. Chest radiography can be a useful tool for demonstrating the presence of a posterior mediastinal mass, which in an infant is usually a thoracic neuroblastoma. A Pediatric Oncology Group study demonstrated that a mediastinal mass was discovered on incidental chest radiographs in almost half of patients with thoracic neuroblastoma who had symptoms seemingly unrelated to their tumors.[28] Abdominal radiography is less often the modality by which a neuroblastoma is discovered; however, as many as half of abdominal neuroblastomas are detectable as a mass with fine calcification.

Ultrasonography. The vast majority of abdominal neuroblastomas in the newborn are diagnosed by ultrasonography, either in the prenatal period, as part of routine surveillance of the fetus, or in the postnatal period, to evaluate an abdominal mass. Although ultrasonography is the modality most often used during the initial assessment of a suspected abdominal mass, its sensitivity and accuracy are less than that of computed tomography (CT) or magnetic resonance (MR) imaging for diagnosing neuroblastoma.

Computed Tomography. CT remains a useful, commonly used modality for the evaluation of neuroblastoma. It can demonstrate calcification in almost 85% of neuroblastomas, and intraspinal extension of the tumor can be determined on contrast-enhanced CT. Overall, contrast-enhanced CT has been reported to be 82% accurate in defining neuroblastoma extent, with the accuracy increasing to nearly 97% when performed with a bone scan.[29]

Magnetic Resonance Imaging. MR imaging is becoming the most useful and most sensitive imaging modality for the diagnosis and staging of neuroblastoma. MR imaging appears to be more accurate than CT for detection of stage 4 disease: the sensitivity of MR imaging is 83%, and that of CT is 43%; and the specificity of MR imaging is 97%, and that of CT is 88%.[30] Metastases to the bone and bone marrow, in particular, are better detected by MR imaging, as is intraspinal tumor extension.[30]

Metaiodobenzylguanidine Imaging. Metaiodobenzylguanidine (MIBG) is transported to and stored in the distal storage granules of chromaffin cells in the same way as norepinephrine. MIBG has been used for scintigraphic imaging of neuroblastoma. The MIBG scintiscan is the imaging study of choice in evaluating the involvement of bone and bone marrow by neuroblastoma, having largely replaced technetium-99m methylene diphosphonate (^{99m}Tc-MDP) bone scans, as approximately 90% of neuroblastomas will take up this radiotracer.[31]

Pathology

Neuroblastoma can be distinguished histologically by the presence of neuritic processes (neuropil) and Homer Wright rosettes (neuroblasts surrounding eosinophilic neuropil). Scattered ganglion cells or immature chromaffin cells may also be seen. The appearance of the tumor cells may vary from undifferentiated cells to fully mature ganglion cells. In addition, neuroblastomas have variable degrees of Schwannian cell stroma, reactive nonneoplastic tissue recruited by the tumor cells.

In 1984, Shimada and colleagues first developed an age-linked classification system of neuroblastic tumors based on tumor morphology in which neuroblastomas were divided into two prognostic subgroups, favorable histology and unfavorable histology. The International Neuroblastoma Pathology Classification (INPC) was devised in 1999 and then modified in 2003,[32] and it is an adaptation of the original Shimada system (Table 91.1). The INPC is an age-linked classification schema that depends on the differentiation grade of the neuroblasts, the cellular turnover rate (mitosis–karyorrhexis index [MKI]), and the presence or absence of Schwannian stroma, and classifies neuroblastic tumors into three morphologic categories: neuroblastoma, ganglioneuroblastoma, and ganglioneuroma.

Table 91.1 Prognostic evaluation of neuroblastic tumors according to the international neuroblastoma pathology classification

International neuroblastoma pathology classification		Prognostic group
Neuroblastoma	**Schwannian stroma-poor**	
		Favorable
<1.5 years	Poorly differentiated or differentiating and low- or intermediate-MKI tumor	
1.5–5 years	Differentiating and low-MKI tumor	
		Unfavorable
<1.5 years	a. Undifferentiated tumor or b. High-MKI tumor	
1.5–5 years	a. Undifferentiated or poorly differentiated tumor or b. Intermediate- or high-MKI tumor	
≥5 years	All tumors	
Ganglioneuroblastoma, intermixed	**Schwannian stroma-rich**	Favorable
Ganglioneuroblastoma, nodular	**Composite Schwannian stroma-rich/ stroma-dominant and stroma-poor**	Unfavorable or favorable (based on nodule histology)
Ganglioneuroma	**Schwannian stroma-dominant**	
Maturing		Favorable
Mature
